likely to be inherited, and sequence variation between homologs will be much less at buried positions than at lipid-accessible positions.

5. Interactions between transmembrane helices differ from those between soluble protein helices

In soluble proteins, the helices of left-handed coiled-coils interact using a mechanism known as *knobs into holes*™ or *leucine zipper packing* (Crick, 1953). This has also been observed to be a common motif in TM helices (Langosch and Heringa 1998). The motif consists of a heptad repeat with hydrophobic residues, particularly leucine and valine, found at the positions buried between the helices. The side chains of these residues interact via extensive hydrophobic interactions, forming "rungs"™ connecting the two helix backbones.

Despite the similar hydrophobicity of internal residues in soluble and TM proteins, and the shared use of leucine zipper packing, there are several differences in the way their helices pack together. TM helices associate more closely than the helices in soluble proteins (Eilers *et al*., 2000). This may be because the residues buried between helices tend to have shorter side chains than those that are lipid accessible (Jiang and Vakser, 2000), allowing closer approach of the helix backbones. In support of this, several groups have identified an inverse relationship between the residue volume and its tendency to be found buried at a helix interface (Javadpour *et al*., 1999, Eilers *et al*., 2000, Adamian and Liang, 2001).

Another major difference between the packing of the two classes of proteins is the presence, in TM proteins alone, of many additional interhelix interactions between two polar residues, or between a polar and a charged residue. Adamian and Liang (2001) described the helix-packing interactions of TM proteins as involving a far more diverse set of polar residues than those of soluble proteins. While, in soluble proteins, they observed three types of interactions between polar groups on interacting helices, in TM proteins, they found 22 different types of polar interaction.

Hence, in addition to the leucine zipper packing, using hydrophobic residues, found in both classes of protein, TM proteins also make use of a wide variety of interactions between polar and charged residues. In TM proteins, the greater importance of polar interactions is to be expected because of their greater strength in the low dilectric lipid environment. Similarly, hydrophobic interactions are likely to be weaker between TM helices, and so they would be expected to play a less important role.

6. Glycine is important in transmembrane helix packing

A striking trend is the strong preference of glycine for buried positions (Javadpour *et al*., 1999, Eilers *et al*., 2000, Adamian and Liang, 2001, Ulmschneider and Sansom, 2001, Eyre *et al*., 2004). The role of glycine has been specifically studied by Javadpour *et al*. (1999). Since its side chain consists of a single H atom, glycine

allows adjacent helices to approach more closely than any other residue. Perhaps as a result of this, in cytochrome c oxidase, it is often found at helix crossings where, as Javadpour *et al*. (1999) have suggested, it may function as a "molecular notch" for orientating one helix against another. This motif also occurs in water-soluble proteins (Richmond and Richards, 1978).

The presence of a glycine residue also exposes the polar backbone atoms of its own chain, facilitating the formation of hydrogen bonds and dipolar interactions (Javadpour *et al*., 1999). These forces are likely to be particularly strong in the hydrophobic environment of the bilayer and hence may play a major role in protein stability. While interactions between the backbone atoms of different helices are rare in both classes of proteins, they seem to be more common in TM proteins than in soluble proteins (Adamian and Liang, 2001). Interactions with the backbone are most common where glycine residues interact.

7. Charged residues show unexpected behavior

Despite the hydrophobic nature of the bilayer, charged residues comprise approximately 8% of all TM lipid-spanning residues (Eyre *et al*., 2004). Surprisingly, charged residues are not necessarily buried, and lysine, arginine, and the polar residue glutamine are more common in lipid-accessible than in buried positions. In addition, as shown in Figure 6(a), when lipid-accessible, charged residues are not necessarily paired with another charge. Hence, the presence of opposing charges within a transmembrane region does not facilitate structure prediction by implying that these residues will be located adjacent to one another. Instead, they form hydrogen bonds with the phospholipid head groups of the membrane or with other residues of all kinds (Eyre *et al*., 2004).

Interestingly, in an investigation of lipid-accessible charged and polar residues, it was found that approximately one third form hydrogen bonds with residues on the same helix (intrahelix) rather than on another one (interhelix) (Eyre *et al*., 2004). These results are summarized in Figure 6(b). The importance of intrahelix hydrogen bonding had not been recognized previously. The role of these intrahelically bonded charged and polar residues is not understood. Since they are so common, there is likely to be some advantage to the presence of charged residues rather than hydrophobic ones at particular positions in the lipid-spanning region. Since they only rarely hydrogen-bond interhelically, this role is unlikely to be associated with maintaining the conformation of the protein by anchoring the TM helices relative to one another. Further work is needed to understand this phenomenon.

8. More structures are needed to fully characterize the properties of transmembrane pore-lining residues

Many TM proteins contain a channel or pore that traverses the membrane through which various substrates are transported. This transport is required for many processes of biological significance, such as the maintenance of cellular ion balance,

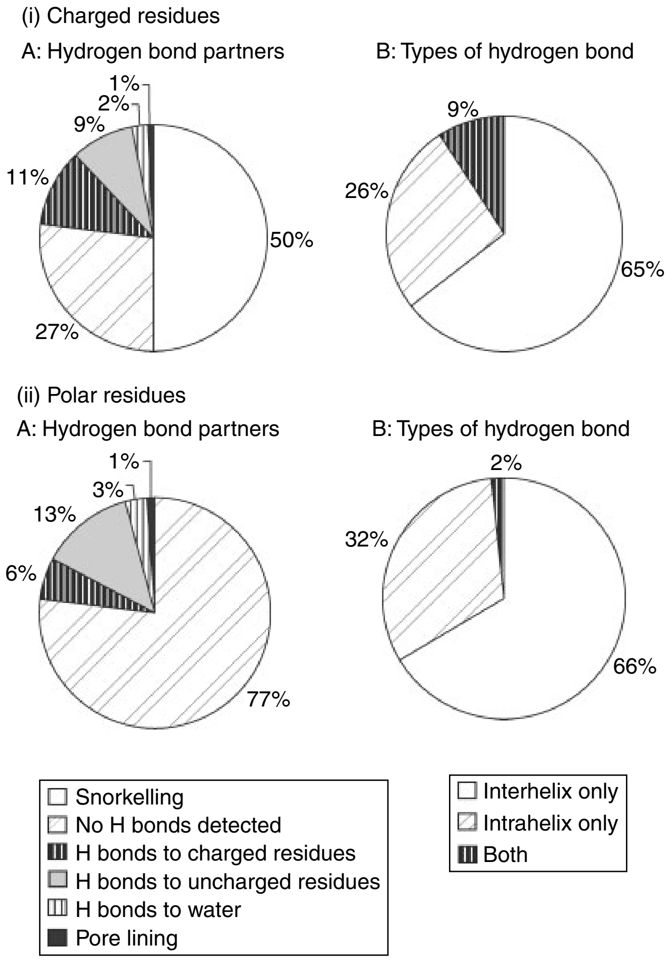

Figure 6 (a) Hydrogen (H) bonding partners and (b) types of hydrogen bonds for (i) the 679 observed lipid-accessible charged residues and (ii) the 2897 lipid-accessible polar residues in 18 TM proteins. For details, see Eyre *et al*. (2004)

nerve conduction, and the uptake of nutrients into cells. Hence, the residues that line these pores are of particular interest since they may give clues about how specificity is achieved.

Pore-lining residues are usually hydrophobic, consisting mainly of isoleucine, alanine, glycine, leucine, and valine (Eyre *et al*., 2004). This is perhaps unexpected, since it is often suggested that, in order to permit the passage of a polar species such as an ion, a channel must be lined with polar residues. It seems likely that hydrophobic residues lining a pore facilitate rapid translocation by minimizing interactions between the transported substrate and the channel walls.

It is difficult to distinguish pore lining from buried residues in terms of either residue type or evolutionary sequence conservation. The major difference between the two groups appears to be an enrichment of pore-lining residues with isoleucine

relative to buried regions (Eyre *et al*., 2004). It seems likely that more pore-containing membrane protein structures will be needed before these residues can be fully characterized and pore-lining helix faces identified from sequence.

9. The number of pore-lining helices and the diameter of the pore can be predicted

In addition to knowledge of pore-lining residues, it is also valuable to understand more general principles such as the size and shape of the pore. Eyre *et al*. (2004) identified linear correlations between

1. the total number of TM helices and the number of pore-lining helices and
2. the number of pore-lining helices and the pore diameter.

As a result, predictions can be made about the proportion of helices that contribute to lining a pore and the likely pore diameter simply from knowledge of the total number of helices. Since the total number of TM helices can now be predicted with relatively high accuracy, this information may facilitate the modeling of membrane proteins.

10. Membrane protein structure prediction

Until recently, there have been few attempts to perform 3D structure prediction on TM proteins. The earliest work in the area analyzed TM helices by comparing their characteristics to those of soluble proteins (Rees *et al*., 1989). This has lead to considerable advances in the automatic prediction of TM helix location and, particularly, through the application of the Positive Inside Rule, of TM protein topology (von Heijne and Gavel, 1988). It is now possible to identify TM helices and predict their topology with an accuracy of greater than 90% (Jayasinghe *et al*., 2001, Jones *et al*., 1994, Moller *et al*., 2001). The next challenge is to develop methods to successfully predict the 3D packing of these helices.

There have been many studies of TM protein structure, as summarized in the previous sections. However, this work has, until recently, been based on few membrane protein structures or simply on their primary sequence. As a consequence, many of the early attempts at TM protein 3D modeling suffered from the same limitations. The importance of the use of data derived from structure and not sequence for prediction is highlighted by the work of Ulmschneider and Sansom (2001), who compared the effectiveness of these two methods in discriminating between TM and non-TM spanning regions. The absence of structural TM data has also led to the use of data derived from soluble protein structures for TM protein modeling.

Despite some limited success (Taylor *et al*., 1994), ab-initio prediction of complete structures has proved difficult. On a more limited problem, Fleishman

and Ben-Tal (2002) used the knowledge of residue environment preferences to predict the likely arrangement of pairs of TM helices with greater than 70% accuracy. Ledesma *et al*. (2002) produced a model for uncoupling protein 1, using computational docking methods. However, in both cases, the pair-potentials used were derived from soluble proteins, shown by many to differ considerably from TM proteins (Rees *et al*., 1989, Eilers *et al*., 2000, Jiang and Vakser, 2000, Javadpour *et al*., 1999, Ulmschneider and Sansom, 2001, Adamian and Liang, 2001, Eyre *et al*., 2004). Pellegrini-Calace *et al*. (2003) used position-specific membrane potentials to perform simulated annealing for the modeling of TM protein structure. However, owing to high computational demands, it is likely to be a few years before the method becomes suitable for the modeling of large TM proteins. In addition, this method also relies upon the docking of protein fragments and residue potentials derived from soluble proteins, which is likely to limit its accuracy. Chen and Chen (2003) have successfully used three-stage Monte Carlo folding methods for small proteins. Other techniques have included homology modeling of proteins belonging to a family in which at least one structure is known (Giorgetti and Carloni, 2003, Nikiforovich *et al*., 2001). Unfortunately, only very few families contain a member with a known structure, so, currently, this method has limited applicability. However, it is likely to become the method of choice as more representative structures are determined.

Now that more TM protein structures have been solved, improved TM structure-based modeling studies can be attempted. There is a need for a simple computationally inexpensive method for the prediction of TM protein structure for all families. Given the considerable differences between the packing of TM and soluble protein helices, it should use data derived from TM proteins alone. Eyre *et al*. (2004b) used a hydrophobic-moment-based approach for prediction, using data derived from the analysis of TM proteins to pack the helices and score possible models. While the method was able to identify the buried face of TM helices with high accuracy, there were major problems with translating this single-helix data into a multiple-helix whole protein model. The work highlighted the importance of helix tilting and kinking in TM protein structure and suggested that more advanced modeling methods are needed that consider these factors. In addition, more channel-containing TM protein structures are needed to enable the characterization of pore-lining residues and their consequent identification from sequence.

11. Conclusions

Over the past few years, there has been an increase in the study of TM protein structure and modeling because of the emergence of a number of new TM protein structures. As with water-soluble proteins, ab initio structure prediction from sequence is challenging. Although we can identify the helices from sequence and predict the TM protein topology, packing pairs of helices by identifying buried and lipid-accessible TM helix faces is difficult. Further work and, crucially, more TM protein structures will be needed before 3D modeling of TM proteins is possible.

Specialist Review

Ab initio structure prediction

David Baker

William R. Taylor
National Institute for Medical Research, London, UK

1. Introduction

The prediction of protein structure from sequence remains one of the most fundamental problems at the interface of physics, chemistry, and biology. Besides its biological importance, its continual fascination derives from the simplicity with which it can be stated: given a protein sequence, what is its three-dimensional structure? This is sometimes called the protein folding problem since one way to approach it is to simulate how a protein would fold within the cell but, as we will see below, this is not the only way to tackle the problem.

The simple statement of the problem hides some assumptions. Specifically, that there will be a well-defined structure to predict and if there is, under what conditions it can be obtained. The latter may include more than the obvious temperature and pH, and could involve posttranslational modifications (cleavage, phosphorylation) or additional cofactors not specified by the sequence (such as a haem group) or the fact that the protein may only be structured in a multimeric state or in combination with another protein. Despite all these caveats, many experiments, beginning with the classic work of Anfinsen (1973), have shown that to a first approximation, the three-dimensional structure of the protein is indeed encoded in its sequence.

The fact that a sequence will generate a well-defined structure does not mean that each sequence will produce a unique structure, and it can be expected that many sequences will fold to similar structures. This property provides an alternative route to structure prediction in which the basic structure of one protein is just modified to accommodate some changes in sequence. For the more obvious similarities, this approach is referred to as "modeling by homology" or for the more difficult problems as the "empirical approach" to structure prediction, in contrast to the more fundamental folding simulations that hope to generate structure ab initio.

Modeling and ab initio prediction effectively lie at extreme ends of a range defined by the size of unit taken as given. In modeling, this is the full-sized protein, whereas in ab initio prediction only the chemical structure of the peptide is assumed. Between these extremes lie many approaches that make use of intermediate-sized fragments, including secondary structure elements or subassemblies of secondary

structure (sometimes called “supersecondary structure”). The latter also range in size from small functional units (called “motifs”) to full protein sized domains. Methods using these intermediate-sized chunks will be referred to generally as “fragment-based” methods.

2. Ab initio structure prediction

The direct simulation approach to protein structure prediction is also the oldest. This is not unexpected since, unlike the empirical or fragment-based methods, it requires no examples to copy. Perhaps the first successful result using this approach was the prediction of the α-helix by Pauling and Corey (1951) before even the first protein structure was known. Pauling, of course, used a physical model but to tackle larger problems an equivalent model encoded in a computer program is preferable.

2.1. *Computational approaches*

2.1.1. Spin bonds or move atoms?

Protein structure can be encoded as a virtual model in two distinct ways. Perhaps the more obvious approach is to have fixed length atomic bonds that can rotate where necessary. The alternative is to have independent atoms that are restrained (In describing molecular calculations, it is usual that the terms “restraint” and “constraint” take specific meanings. “Restraint” implies an imposed tendency toward a specific value, while “constraint” implies that the quantity has a fixed value.) to maintain required bond lengths.

The rotation approach, while more intuitive, is difficult to animate since a rotation around any bond will displace all of the following parts of the protein in an unnatural way. To rotate a bond in a chain such that there are only local perturbations in conformation is quite a difficult computational problem, especially when the effect of nonlocal interactions (involving remote parts of the sequence) must be taken into consideration.

The alternative is to displace each atom individually under the combined influence of all local and nonlocal effects. If the local contributions are dominated by a restraint to maintain connecting bond lengths and the angle between these bonds, then the overall result can replicate a bond rotation.

2.1.2. Slide or jump?

In both the above approaches, each rotation or move is considered in turn and the structure is displaced slightly from its current conformation into a new conformation. A choice must be made for the size of each displacement that equates with the time period between moves and the temperature of the simulation. It might be thought desirable to have the system evolve as smoothly as possible, which requires having a very fine time step. However, this directly increases the computation time of the simulation and may prevent any significant structural changes being observed in the available time.

Two approaches can be adopted to avoid this. One is to make the program run faster using a simplified model (considered in the following section) and the other is to greatly increase the size of the displacements and ignore the continuity between them. This is more like a random sampling of possible conformations and is called "Monte Carlo" (after the spiritual home of random number generation). The random component means that, even if the old conformation had a low energy, the new conformation might have a high energy. To avoid these undesirable states, a cutoff on the energy of the conformation can be applied, but only sometimes. Whether to accept or reject a conformation is determined with a probability that is a function of its energy. So some high-energy conformations are occasionally accepted, just as some low-energy conformations are occasionally rejected.

2.1.3. Simulate or select?

Given a finite computational resource, it would be possible to run a single simulation for a long time or to run multiple simulations for a shorter time. In the former, if the protein folded quickly, time would be wasted: either the correct conformation is obtained, in which case further simulation is not informative or the structure may be trapped in an incorrect conformation from which it cannot escape. Running a larger number of simulations can increase the range of conformations that are generated, giving an idea of how reproducible (and maybe how correct) any one particular solution might be.

This strategy can also be taken to an extreme using no, or minimal dynamics. Given an algorithm to generate compact protein-like structures, then a large number of these can be created and simply evaluated to identify those that have low energy. This is somewhat like a one-jump Monte Carlo approach, and to have any hope of getting a good prediction in one-shot, a very large number of candidate structures need to be generated.

Rather than rely on getting a reasonable structure on the first pass, a number of good structures can be selected and used as a base from which to generate further variations. This is rather like Monte Carlo in parallel and can be implemented using an optimization strategy called the Genetic Algorithm (GA) (Dandekar and Argos, 1994; Petersen and Taylor, 2003).

2.1.4. Out of hyperspace

The methods described above have in common the need to generate an initial starting conformation for the chain. The specification of this can affect either how the molecule folds or, more directly, its actual conformation in the one-shot approaches. Clearly, those that generate most models will be less sensitive to the initial configuration, however, there is an alternative approach based just on distances that avoids it completely.

Not unreasonably, this method is known as Distance Geometry (DG), and is widely used in calculating structures based on NMR data, which come in the form of interatomic distances. When the distances are uncertain (as all predicted distances will be to some extent), then the method requires careful handling. A reasonably

robust implementation has been devised using a combination of DG with refinement in high-dimensional space (Aszódi and Taylor, 1994).

Although the method avoids a specific starting conformation, it can still be run multiple times (with different random displacements on the starting distance set) to give an idea of the uniqueness or spread of the final models. Because DG has no constraint to follow a folding pathway, it is prone to generate tangled or even knotted structures. In folding simulations, there is a bias to form sequentially local contacts, which reflect what is seen in known structures. Without this bias, DG may waste time looking in biologically infertile regions of conformational space.

2.1.5. Statistical model

Like DG, there are some interesting models for proteins do not even have a tangible representation of the structure at all. These tend to be statistical in nature, dealing with the probabilities of multiple options. These include: the self-consistent field (SCF) method (Finkelstein and Reva, 1991), associative memory Hamiltonians (AMH) (Friedrichs *et al*., 1991), and artificial neural nets (ANN) (Holbrook *et al*., 1993). All of these iteratively refine a set of probabilities. The SCF method takes a physical framework and refines the probabilities of residues to lie in particular places, converging to a self-consistent result where each point is occupied by only one residue. AMH and ANN methods are related techniques in which the probabilities are represented by a set of multidimensional vectors and a set of weights in a network, respectively. Both these methods are more typically "trained" on native proteins and are used to evaluate models generated by other means.

2.2. Molecular models

The preceding section has concentrated on the mechanics of manipulating structures with little reference to the molecular models themselves. In this section, some representations of proteins are described, and almost all of them can be used in combination with any of the computational strategy described above.

The geometric specification of the models and the description of their internal interactions range from the very simple – single sphere per residue with only two residue types (hydrophobic/hydrophilic) – to complex quantum mechanical representations. The degree of model complexity directly affects the computation time required, limiting the length of simulation or the number of models that can be calculated or the size of protein/peptide that can be studied.

In this section, we will ignore quantum calculations (which are typically only performed on very short peptides). We will also give scant consideration to the molecular force calculations used in conventional molecular dynamics calculations (*see* Article 74, **Molecular simulations in structure prediction**, Volume 7). Instead, we will concentrate on simplified molecular representations and their simplified "forces" as it is only with these that a large number of calculations can be performed on proteins of even average size.

2.2.1. Lollypop models

One of the earliest attempts to simulate the folding of a small protein used a simplified model of the chain with two points (spheres) per residue. One representing the α-carbon position and the other representing a residue centroid (Levitt, 1976). The resulting model looked rather like a string of lollypops from which the model derived its unofficial name. An even simpler lollypop model can also be based on just a single point per residue if it is assumed that the side-chain centroid can be approximated by an extension of the line bisecting the angle formed by three consecutive α-carbon atoms.

While computational speed can be gained using a simplified model, this is directly traded against accuracy in the packing and other interactions of residues. In the lollypop model, flexibility is lost in the side chain, which may make the difference between packing a large residue in the core and excluding it. In addition, the specificity of exact hydrogen bonding is also lost, which means that only general preferences for residues to interact can be expressed.

It can be argued that the overall structure of proteins is dominated by the formation of a hydrophobic core and if this can be captured using only simple residue properties, then protein-like structures will be generated. However, for any given sequence, there are many ways of creating a good hydrophobic core and without the fine specificity of side-chain interactions, it is probably impossible to discriminate one from the other.

2.2.2. Secondary structure models

Secondary structure elements in proteins fix a number of residues into a relatively rigid substructure. If these elements can be predicted, then the conformational freedom of the chain becomes greatly reduced. Over the years, many methods have tried to exploit this advantage.

One approach to this is to move the secondary structures as rigid bodies and “dock” them together to build up a structure. This is computationally feasible for α-helices, which can behave as independent units. However, it is difficult to apply the approach to β-structure. An alternative approach is to take a predefined general framework over which the secondary structure elements can be allocated in a combinatorial way and the resulting structures filtered.

3. Empirical approach

3.1. Combinatorial secondary structure packing

In the late 1970s, the protein folding problem, tackled using direct folding simulation, was generally considered to be computationally intractable due to the large number of atomic interactions that occur even in a small protein. To find a way around this problem, an approach was developed that did not calculate the interactions from first principles (ab initio) but instead compared the model interactions to what had already been observed in known protein structures. This approach was based on a detailed analysis of secondary structure packing in proteins (Cohen

et al., 1981) and began what was later to be called the empirical approach to protein structure prediction. The approach was applied to simplified models constructed from secondary structure elements. By considering many different secondary structure packing combinations, it was possible to select a limited number of structures that included the true (native) protein structure (Cohen *et al*., 1980). Although initially applied only to a subclass of proteins, the method was later extended to other classes (Cohen *et al*., 1982; Taylor, 1991), including membrane proteins (Taylor *et al*., 1994).

These early applications of the empirical approach relied on finding clusters of hydrophobic residues that packed to form a hydrophobic core; however, the same principle can be applied at other levels from pairs of residues, through clusters of residues to the assessment of an intact structure.

3.2. Fragment-based approach

3.2.1. The ROSETTA program

The most successful approach to ab initio structure prediction over the past 6 years based on the CASP tests (*see* Article 73, **CASP**, Volume 7) is called ROSETTA. Rosetta is based on a model of folding in which short segments of the protein chain flicker between different local structures, consistent with their local sequence, and folding to the native state occurs when these local segments are oriented such that low free-energy interactions are made throughout the protein (Simons *et al*., 1997). In simulating this process, it is assumed that the ensemble of local structures sampled by a given sequence segment during folding is roughly approximated by the distribution of local structures sampled by that sequence segment in native protein structures. A list of possible conformations is extracted from experimental structures for each nine residue segments of the chain, and protein tertiary structures are assembled by searching through the combinations of these short fragments for conformations that have buried hydrophobic residues, paired beta strands, and other low free-energy features of native proteins. This strategy resolves some of the typical problems with both the conformational search and the free energy function: The search is greatly accelerated as switching between different possible local structures can occur in a single Monte Carlo step, and less demands are placed on the free energy function since local interactions are accounted for in the fragment libraries.

To generate structures consistent with both the local and nonlocal interactions responsible for protein stability, 3 and 9 residue fragments of known structures with local sequences similar to the target sequence were assembled into complete tertiary structures using a Monte Carlo simulated annealing procedure (Simons *et al*., 1997). The scoring function used in the simulated annealing procedure consists of sequence-dependent terms representing hydrophobic burial and specific pair interactions such as electrostatics and disulfide bonding and sequence-independent terms representing hard sphere packing, alpha-helix and beta-strand packing, and the collection of beta-strands in beta-sheets (Simons *et al*., 1999).

For each of 21 small, ab initio targets, 1200 final structures were constructed, each the result of 100 000 attempted fragment substitutions. The five structures submitted for the CASP III experiment were chosen from the approximately 25

structures with the lowest scores in the broadest minima assessed through the number of structural neighbors (Shortle *et al*., 1998).

The results were encouraging: highlights of the predictions include a 99-residue segment for MarA with an rmsd of 6.4 A to the native structure, a 95-residue (full length) prediction for the EH2 domain of EPS15 with an rmsd of 6.0 A, a 75-residue segment of DNAB helicase with an rmsd of 4.7 Å, and a 67-residue segment of ribosomal protein L30 with an rmsd of 3.8 Å. Rosetta predictions in the CASP4, CASP5 and CASP6 international blind prediction experiments were even more promising. These results suggest that ab initio methods may soon become useful for low-resolution structure prediction for proteins that lack a close homolog of known structure.

3.2.2. Refining rough structures

The challenge for the past 4 years has been to refine the low-resolution models into accurate high resolution structures using an all-atom representation and a physically realistic potential. This is necessary because of the critical role steric packing interactions play in protein structure and stability; without explicitly modeling these interactions, the best that can be hoped for is that one of a several plausible models with the hydrophobic residues buried, strand paired, and so on. Full-atom refinement is very challenging because the landscape being searched is very large and very bumpy (even 1-Å shifts from the native structure, presumably the global minimum, can produce huge energy spikes if atoms overlap one another).

A protocol for full-atom refinement has been developed with the Rosetta software package that uses a Monte Carlo with minimization (MCM) optimization protocol for the backbone coordinates, a Monte Carlo search through side-chain rotamer possibilities for the side-chain coordinates, and a potential dominated by a Lennard Jones potential, an implicit solvation model, and an explicit orientation-dependent hydrogen bonding term. This full-atom refinement protocol has been used successfully in protein–protein docking calculations (Gray, 2003) (results from the recent CAPRI V challenge are particularly notable), and supplemented with sequence optimization methodology, to design with atomic accuracy a sequence that adopts a novel fold (Kuhlman, 2003).

An exciting result from CASP6 is that for the first time in a blind test, high-resolution refinement significantly improved a low-resolution model, leading to a prediction of almost atomic level accuracy (1.5 A rmsd) in which features of the native core packing arrangement are partially reproduced. Over the next few years, it is hoped that with continued improvements in methodology and increases in computer power ab initio methods can consistently produce atomically accurate models for small proteins, which would greatly increase their application to real-world problems.

Specialist Review

Score functions for structure prediction

Richard A. Goldstein
National Institute for Medical Research, London, UK

1. Introduction

Protein structure prediction is often divided into homology modeling (*see* Article 66, ***Ab initio* structure prediction**, Volume 7, Article 70, **Modeling by homology**, Volume 7, and Article 72, **Threading for protein-fold recognition**, Volume 7), fold recognition, and ab initio prediction, depending upon the availability of proteins of related sequence and structure and the resolution required tasks. For all three, one needs (1) a space of possible structures, (2) a method for searching through this space, and (3) a criterion for selecting one (or more) of those structures as the prediction. The selection criterion is often in the form (or can be put in the form) of a "score function", a method for producing a score quantifying how well the target sequence matches a given structure. The form of the score function depends upon the structure space and the search strategy; particularly important is the manner in which the possible structures are represented. Is the structure represented to atomic-level accuracy, or by a highly simplified model? Are all angles and bonds free to vary, or are there only discrete possibilities? Simplified, discretized representations (e.g., representing the structure as a string of beads, each residue represented by one bead) make the search problem more tractable (we do not have to worry about searching over all conformations of the side chains), but limits the details that can be used in the score function. Simpler score functions, however, tend to be faster to compute, allowing for more exhaustive and far-ranging search methods. In addition, simpler score functions may be easier to create, as described below. In this review, we discuss various approaches to generate score functions. While our emphasis will be on such functions, some discussion of the protein representation cannot be avoided.

The representation and the corresponding score function depends upon the nature of the problem one is trying to solve; homology modeling, where we are interested in atomic-level detail based on the structure of a related protein, obviously requires an atomic-resolution representation, while we might be satisfied for a rougher representation for an ab initio prediction. We do not have to be consistent in our

methods, and can use more detailed representations as the prediction goes through successive stages (Feig *et al*., 2000). As homology modeling is represented in a separate chapter (*see* Article 70, **Modeling by homology**, Volume 7), we focus in this review on scoring functions for fold recognition and ab initio prediction. There are approaches that, while formally "score functions", will not be considered here. Feed-forward neural networks, for instance, represent a particular class of highly flexible functions over an extremely large dimensional space, with a potentially huge number of adjustable parameters generally determined with a data-fitting algorithm. We will restrict our focus to score functions that, given a sequence and a three-dimensional structure, calculate the score of the sequence when it assumes the given structure.

The construction of a score function involves two distinct steps: the choice of a "functional form" for the function, generally involving a (potentially large) set of adjustable parameters, and the determination of those parameters. The choice of functional form is especially tied up with the representation of the protein structure – obviously a score function that depends upon atomic interactions requires an atomic-resolution representation.

The most obvious approach to generating a score function is based on the so-called thermodynamic hypothesis that states that proteins folded into the conformation of lowest free energy (Anfinsen, 1973; Govindarajan and Goldstein, 1998). If this hypothesis is correct, the value of the free energy would be the perfect score function. Such a score function would also provide the most insight into the physicochemical interactions that govern the folding process. Beyond questions about the validity of the thermodynamic hypothesis, there are additional challenges generating sufficiently accurate free-energy values (entropic terms, including the hydrophobic effect, and conformational and vibrational entropy, are especially difficult) sufficiently rapidly to perform an effective conformational search.

Given the problems with generating an accurate free-energy function, alternative strategies have arisen. We have one great resource at our disposal: we know many right answers. Embodied in the protein structure databases are many sequences with their corresponding structures. A number of different "knowledge-based" techniques have been developed in which a representative "training set" of known protein structures is assembled, a score function is produced on the basis of an analysis of this training set, and the method evaluated on a separate "test set" of proteins (Tanaka and Scheraga, 1976). There have been three approaches to constructing score functions based on the set of known protein structures; thermodynamics, statistics, and machine learning. In the following, we describe some of the functional forms that have been used for score functions, and outline how these approaches are used to determine the values of the various parameters.

There is a problem of sign convention. Researchers who think of score functions generally associate high-scoring structures as likely predictions. Those who think in terms of approximate free-energy functions associate structures with low energy as likely predictions. I will use the term "score function" to imply a high score means a better structure. This score function will then be the negative of any energy function.

2. Functional forms

The score function determines a numerical score for how well a target protein (with sequence $\{A_i\}$) is compatible with a structure (with coordinates $\{\vec{x}_i\}$). As described above, the value of the free energy is often used as a basis for the (negative of the) score function. Often, this function takes a form similar to those in use in molecular modeling (*see* Article 74, **Molecular simulations in structure prediction**, Volume 7):

$$\text{Score} = -\Delta G = -\left(\Delta G_{\text{covalent}} + \Delta G_{\text{VdW}} + \Delta G_{\text{electrostatic}} + \Delta G_{\text{hydrophobic}} + \cdots\right) \tag{1}$$

where $\Delta G_{\text{covalent}}$, ΔG_{VdW}, $\Delta G_{\text{electrostatic}}$, and $\Delta G_{\text{hydrophobic}}$ represent the contributions to the free energy from the covalent bond geometry (including bond stretching and both bond and dihedral angles), Van der Waals interactions, electrostatic interactions (including hydrogen bonds), and interactions with the solvent respectively. Other terms can be added as appropriate. Each of these have standard forms, with parameters that have been adjusted based on ab initio quantum mechanical calculations and/or observed properties of various molecules, although the parameters could also be derived using the knowledge-based methods described below. The sequence of the target protein is included by atomic composition and the covalent connections between the atoms making up the residues. Of these terms, interaction with the solvent is potentially the most problematic. Issues of computational resources generally precludes the use of an atomic-resolution description of the solvent, so simpler approximations are made. For instance, calculations can be made of atomic surface area exposed to the solvent, and $\Delta G_{\text{hydrophobic}}$ calculated on the basis of observed linear relationships between hydrophobic free energy and this exposed area. It is also possible to use more complicated models of the interaction with solvent, such as the Generalized Born (GB) continuum solvent model (Still *et al*., 1990). It is possible to add and change terms to include observed properties of proteins, for instance, including terms that make the protein more likely to be "protein-like", that is, to be compact and to have the right proportions of local, secondary, and supersecondary structure.

While we are not able to use these realistic forms for searching over a large range of possible structures, progress has been made in using these potentials for identifying the correct structure from amongst a large set of decoy structures (Dominy and Brooks, 2002; Felts *et al*., 2002), as well as refining more approximate structures (Feig *et al*., 2000). Another advantage is that such a method, if successful, would provide much information about how protein structures are determined. In addition, these potentials do not need a database of known structures, which means that they are immune to problems of limited and biased protein structure databases.

The physicality causes one further limitation. Often, information is available that is not physicochemical in nature, for instance, from experimental observations. While this information can be put in the form of an energy function and in this way added to the prediction scheme, such an approach must be done in an ad hoc way,

as there is no natural approach to include nonphysical interactions in a realistic physical scheme.

As described above, this function would require an all-atom representation of the protein conformation as well as a complicated search strategy. For these reasons, simpler functional forms are often used, especially for fold recognition and ab initio prediction. One of the more common encodes the contacts made between different residues in the protein, with a general form similar to

$$\text{Score} = -\sum_{<ij>} \Delta G_{\text{contact}}\left(A_i, A_j\right) u(\vec{x}_i, \vec{x}_j) \tag{2}$$

where $\Delta G_{\text{contact}}(A_i, A_j)$ represents the effective free energy of interaction that would occur between amino acid A_i and amino acid type A_j, $u(\vec{x}_i, \vec{x}_j)$ is 1 if and only if residues i and j "interact" according to some criterion, and the sum is over all pairs of residues. Numerous criteria have been used for interaction, generally involving fudicial points on the two residues (e.g., α-carbons, β-carbons, center of mass of the side chain, or any heavy atoms) within some specified distance. Similar to this contact potential is a distance-dependent potential, where the contact energy is dependent upon the distance between the interacting residues.

Studies have shown that pairwise contact energies such as described in equation (2) are insufficient to correctly predict protein structures (Vendruscolo and Domany, 1998). Indeed, more complicated terms can be included, such as adding higher-order terms or anisotropic interactions (Buchete *et al*., 2003). For instance, three-body terms would involve sums over all triplets of amino acid with a contact potential depending upon all three residues. The contact potential $\Delta G_{\text{contact}}(A_i, A_j)$ can also be made more complex by including information regarding neighboring residues, predicted or structure-based secondary structure or solvent accessibility, and so on. Finally, care must be taken in situations in which contacts are not pairwise-additive, such as cysteine–cysteine interactions – it is possible for one cysteine to make contact with multiple other cysteines, so that the presence of one disulfide bond must eliminate the possibility of further disulfide bonds with these residues.

The above scoring function, while certainly simpler to calculate than the molecular-modeling score function, still necessitates a complicated strategy for searching over possible conformations. A simpler strategy is to consider the propensity for various residues to be in various structural "contexts" (Bowie *et al*., 1991):

$$\text{Score} = -\sum_{i} \Delta G_{\text{context}}\left(A_i, C_i\right) \tag{3}$$

where $\Delta G_{\text{context}}(A_i, C_i)$ represents the free energy of residue type A_i when in context C_i, where C_i can include secondary structure, solvent accessibility, character of nearby residues, and so on. The advantage of such an expression is that it is much more amenable to fast searches based on dynamic programming algorithms, as is used in sequence–sequence alignments.

There has also been some work on extremely simple functional forms, attempting to capture the most basic observed properties of proteins, such as compactness, the

placement of hydrophobic residues, and the presence of local structures (Huang *et al*., 1995; Yue and Dill, 1996; Srinivasan and Rose, 1995). One advantage of such schemes is that they are often designed in association with a rapid method for exploring conformation space, and have the potential to yield comprehensible insights into the nature of the relationship between sequence and structure.

All of these score functions are to some extent "physical" functions in that they try to model the free energy of the protein in some simplified manner. There are other score functions that owe their construction more to machine learning than to physical chemistry, generating a score function that explicitly includes information about proteins of known structure. An example of this is neural-network-based score functions. For instance, one can construct a score function that seeks to model how well the target protein's structure matches that of "template" proteins through the use of an "Associated Memory Hamiltonian" (Friedrichs *et al*., 1991).

There are many methods of introducing supplementary information, besides the sequence of the target protein, into the score function through the inclusion of additional terms. Experimentally determined distance constraints, for instance, are a staple of molecular modeling techniques, and have found use in structure prediction. Similarly, predictions made from other methods, such as neural-network-predicted secondary structure, can be included. Hybrid methods exist that combine the sequence-structure score functions discussed here with traditional sequence–sequence methods, increasing the score when the target protein has some degree of sequence similarity with the template protein. Finally, the availability of large numbers of evolutionarily related (homologous) proteins, likely forming highly similar structures, can provide much information. This has been used by searching for a single structure that is compatible with the set of homologs (Goldstein *et al*., 1993), encoding the conservation and variation at each location as an element of the target protein sequence (Defay and Cohen, 1996), and looking directly at how compatible the evolutionary substitutions observed at each position are with the local structure at that position (Goldman *et al*., 1996).

3. Determination of parameters

The functional forms described above all involve particular parameters that must be determined. The atomic-resolution formulation can rely on matching calculations and observations for a wide range of molecules. Most of the other forms, however, require an analysis of the known database of protein structures for the determination of these parameters. As described above, three approaches are in common use: thermodynamic, statistical, and machine learning. These approaches will be discussed in turn below.

3.1. *Thermodynamic approach*

The thermodynamic approach seeks to determine an appropriate free-energy function from the databases of known protein structure. The archetypal example is "potentials of mean force". The Boltzmann distribution states that at equilibrium

at a given temperature, the probability $f(S_i)$ that a system will be in state S_i with free energy $G(S_i)$ is given by

$$f\,(S_i) = \frac{\exp\left(-G\,(S_i)\,/kT\right)}{Z} \tag{4}$$

with k equal to Boltzmann's constant, T as the temperature, and Z is the partition function equal to $Z = \sum_{i'} \exp\left(-G(S_{i'})/kT\right)$, where the sum is over all possible states of the system. The above can be written as

$$G\,(S_i) = -kT \log\left[f\,(S_i)\right] - kT \log Z \tag{5}$$

that is, the free energy of a state can be calculated (up to an additive constant) on the basis of the probability of the system being in that state at thermal equilibrium.

Although the Boltzmann distribution refers to fluctuations in a *single system* or ensemble of *identical systems* at thermal equilibrium, we now extrapolate to the distribution of a *particular interaction* s_i in the ensemble of a large set of *different systems*, corresponding to various protein structures in their *ground* state, that is, *ignoring* any fluctuations. We compare the probability $f(s_i)$ that this interaction is found in this set of proteins compared with the probability $f_{\text{ref}}(s_i)$ that it occurs in a prespecified reference state. Computing $\Delta G(s_i)$, the difference between $G(s_i)$ in the set of proteins and $G_{\text{ref}}(s_i)$ in the reference state (both given by equation (5) with the appropriate value of $f(s_i)$) and neglecting the partition function, yields (Sippl, 1990)

$$\Delta G\,(s_i) = RT \log \frac{f\,(s_i)}{f_{\text{ref}}(s_i)} \tag{6}$$

In reality, we do not have the probabilities $f(s_i)$ but only the observed frequencies. We can correct for the limited nature of our data by considering (Sippl, 1990)

$$f\,(s_i) = \frac{1}{1+m\sigma} f_{\text{background}}\,(s_i) + \frac{m\sigma}{1+m\sigma} f_{\text{obs}}\,(s_i) \tag{7}$$

where m is number of observations, $f_{\text{obs}}(s_i)$ is the observed frequency of interaction s_i, $f_{\text{background}}(s_i)$ is a suitably constructed estimated frequency of s_i neglecting the amino acid dependence of the interaction, and σ is a parameter representing our confidence in the observed data. As can be seen, $f(s_i)$ changes from $f_{\text{background}}(s_i)$ to $f_{\text{obs}}(s_i)$ as more data becomes available.

This approach can be used on almost all of the different functional forms, although most uses of this method has involved pairwise interactions, including contact and distance-dependent potentials, at either residue or atomic resolution.

Although the derivation as stated lacks rigor, this approach has been justified using either a "quasi-chemical approximation" (Miyazawa and Jernigan, 1985) or evolutionary considerations (Finkelstein *et al*., 1995). (According to the latter justification, the "temperature" in equation (6) is not the temperature of the organism, or the protein when crystallized, or anything directly related to a physical temperature.) There are, however, still issues that remain. First, it is not clear what

is the reference state used for calculating $f_{\mathrm{ref}}(s_i)$. Should it represent the target protein in its unfolded state, or a set of proteins in random structures, or something else? One of the main differences between different implementations of this approach is in the choice of this reference state. More importantly, in the potential of mean force approach, the strength of each interaction is influenced by all other interactions with which it is correlated. (This is, for instance, how hydrophobicity can be included in the pair contact term; contacts between residues are negatively correlated with contacts between those residues and solvent, and thus the hydrophobicity of a residue will increase its apparent attraction for other residues, even in the absence of interactions between these residues.) Any correlation between the various interactions in the potential lead to double-counting; each interaction will be included explicitly in the potential as well as implicitly, through its effect on the strength of the various other interactions. As a result, this approach requires that the various terms in the potential not only be additive, but that their occurrences be *uncorrelated* in the ensemble of database proteins. This is unlikely to be true. For instance, residues found in β-sheets are more likely to be in contact with each other, simply because β-sheets have a tendency to be clustered in the interior of the protein. More subtly, it has been conjectured that interactions in the folded state are highly correlated as a way of assisting the folding process (Go, 1983; Bryngelson and Wolynes, 1987). Correlations increase as the energy function becomes more complicated. Approaches to examine the validity of the thermodynamic approach have yielded mixed results (Skolnick *et al*., 1997; Thomas and Dill, 1996). Despite the doubts raised, this method has been popular and has yielded success in fold recognition. One positive aspect has been that, by ignoring correlations between terms, the parameters of the model are rather well behaved. This might be less of an advantage as more data becomes available.

3.2. *Statistical approach*

The statistical approach is similar in form to the thermodynamic approach, but differs in underlying basis, resembling the formulations used for sequence–sequence alignments.

The easiest example is with the simple single-body terms described in equation (3), describing the propensity $\Delta G_{\mathrm{context}}(A_i, C_i)$ for any amino acid A_i to be in a given structural context C_i. This is used to evaluate the probability that sequence $\{A_i\}$ would be found in structure $\{\vec{x}_i\}$. This is in fact a conditional probability $P(\{\vec{x}_i\} \mid \{A_i\})$ that a protein would form structure $\{\vec{x}_i\}$ given that its sequence is $\{A_i\}$, where the probability is meant as a measure of our ignorance and uncertainty. The predicted structure can be seen as, in this sense, the structure with the highest value of this probability.

The conditional probability can be inverted using Bayes law to

$$P(\{\vec{x}_i\} \mid \{A_i\}) = \frac{P(\{A_i\} \mid \{\vec{x}_i\})\ P(\vec{x}_i)}{P(\{A_i\})} \tag{8}$$

Often, the "prior" term $P(\{\vec{x}_i\})$ representing the a priori probability of this structure is neglected, although this is not necessary. (In fact, it is possible to use this term to

include additional understanding of the nature of protein structures, such as they are compact and have significant secondary structure (Simons *et al*., 1997).) Neglecting this term yields the result that we want to find the structure $\{\vec{x}_i\}$ that maximizes $P(\{A_i\} \mid \{\vec{x}_i\})$, that is, the conditional probability that the given sequence would result from that structure, divided by $P(\{A_i\})$, the probability that the structure would occur in a random structure. If we now assume that the choice of amino acid at location is independent, that is, the probability of any amino acid at a given location depends only upon the nature (or context) of that location C_i, we can factor $P(\{A_i\} \mid \{\vec{x}_i\})$ over all locations. Doing the same thing with $P(\{A_i\})$ (which is, anyway, independent of structure) yields

$$P(\{A_i\} \mid \{\vec{x}_i\}) \approx \prod_i \frac{P(A_i|C_i)}{P(A_i)} \tag{9}$$

or

$$\log(P(\{A_i\} \mid \{\vec{x}_i\})) \approx \sum_i \log\left(\frac{P(A_i|C_i)}{P(A_i)}\right) \tag{10}$$

which is the same as the functional form of equation (3), where

$$\Delta G_{\text{context}}(A_i, C_i) = \log\left(\frac{P(A_i|C_i)}{P(A_i)}\right) \tag{11}$$

This approach can be applied to a wide variety of functional forms, and in the case of pair potentials yields a result similar to the thermodynamic approach. In contrast to the thermodynamic approach, however, the assumptions are more clearly stated, meaning that they can be more easily evaluated and, if necessary, corrected (Simons *et al*., 1997).

3.3. *Machine-learning approach*

The thermodynamics and statistics approaches described above are based on statistics of correct structures, including random structures as, at most, normalizing parameters. In contrast, one can treat protein structure prediction as a discrimination problem, finding a scoring function that separates correct from incorrect structures. In this manner, the “best” scoring function is one that maximizes this discriminatory power. This leads to a more symmetric handling of correct and random structures.

This approach has proceeded through a number of different directions. One method has been to maximize the minimum “gap” between the worst scoring correct structure and the best scoring incorrect structure, or alternatively, by maximizing the minimum gap adjusted for the difference between the correct and incorrect structure, so that more dissimilar structures have worse scores (Tobi and Elber, 2000; Maiorov and Crippen, 1992; Micheletti *et al*., 2001; Crippen, 1991; Vendruscolo and Domany, 1998).

There is a concern whether the “maximin” method may be overly sensitive to the (possibly extremely small) subset of high-scoring incorrect structures. An

alternative approach has been to look at the distributions of scores generated with correct and incorrect structures, model these distributions with a functional form, and try to optimize the characteristics of this particular functional form. The first approach with this method, based on ideas from spin-glass theory, described the distribution of scores for incorrect structures as a Gaussian distribution, and then maximized the so-called Z-score, defined as the difference between the correct score and the average of the random scores, divided by the standard deviation of the random scores (Goldstein *et al.*, 1992b; Goldstein *et al.*, 1992a). As the potential was derived for a large ensemble of proteins of known structure, both the difference between correct and average and the standard deviation of the random scores were averaged over the training set, to allow a closed-form solution for the optimal score function. Other methods have been described, such as maximizing the harmonic mean of the Z-score (Mirny and Shakhnovich, 1996) or maximizing the probability that the highest-scoring structure is correct (Chiu and Goldstein, 1998a). This optimization procedure has been used for a wide range of different functional forms, from contact potentials (Goldstein *et al.*, 1992b; Mirny and Shakhnovich, 1996) to Associative Memory Hamiltonians (Goldstein *et al.*, 1992a) to more realistic energy force-fields (Liwo *et al.*, 1997). This method can be used on the statistically different problem of inverse folding, finding those sequences most likely to fold into a given structure. There is no a priori reason to believe that the optimal score function for inverse folding would be the same as for fold prediction, and test cases with lattice proteins indicate that such optimized score functions can actually outperform the perfectly accurate free energy function (Chiu and Goldstein, 1998b).

One general problem with such optimization schemes is that they optimize what they are asked to optimize, not necessarily what is desired to be optimized. For instance, in Z-score optimization, increasing the scores of the most unlikely, low-scoring structures can increase the Z-score by shrinking the standard deviation of the scores of random structures, even if this compromises the gap between the correct structures and the best, high-scoring structures (Chiu and Goldstein, 2000). This problem has been approached by iterative methods to more realistically model the higher-ranking (lower energy) states (Koretke *et al.*, 1996; Hao and Scheraga, 1996). In contrast to the statistical and thermodynamic approaches, it is also less obvious how to adjust for the limited statistics available in current sets of protein structures. An additional problem is that such discrimination methods distinguish between a "correct" fold and a diverse set of incorrect folds. This latter set is highly heterogeneous, and may be poorly represented by a single distribution.

A major advantage of the optimization scheme, however, is that it determines the "best" set of parameters, given all of the correlations between the different terms in the set of known structures. As a result, it does not make the same assumptions of independence required in the thermodynamic and statistical approaches. This makes the scheme ideally suited to the mixing of heterogeneous types of information, including data regarding predicted local structure, experimental observations, information of related sequences, and so on. The optimization strategy automatically weights the various physical and nonphysical terms in the appropriate way, accounting for the correlations between them.

4. Future directions

Previous work in the development of these score functions has involved a balance between realism and simplicity. Physics-based potentials provide the ultimate realism, and, in principle, the most accuracy and insight, but the requirement for an atomic-level description of the protein conformation has restricted their use to homology-modeling and limited searches over decoy structures. More complicated knowledge-based functions require more data to fix the various parameters, as well as more computer resources for performing conformational searches. This has meant that much of the progress in fold recognition and ab initio folding has involved highly simplified score functions. This may change rapidly as computational resources become more available and the set of proteins of known structure expands. This may enable more complicated score functions with many more adjustable parameters. The rise in complexity is likely to extend to more than score functions. It will be necessary to deal with the complexity of the data, including various biases and correlations, as well as with the nonadditive nature of the various interactions. This work will not proceed in isolation. In particular, ways of preprocessing the sequence data, including predictions of local structure, analysis of related sequences, and so on, is likely to increasingly provide relevant information for the scoring function.

Specialist Review

Protein domains

Jaap Heringa

Vrije Universiteit, Centre for Integrative Bioinformatics VU, Amsterdam, The Netherlands

1. Introduction

Protein domains are independent or semi-independent folding units of protein structure that serve as structural building blocks of proteins. Their size varies from 36 amino acids in the protein E-selectin to 692 residues in lipoxgenase-1 (Jones *et al*., 1998). Most domains observed in nature have less than 200 residues, with an average domain size of about 100 residues. While smaller domains of less than 50 residues are often structurally reinforced by disulfide bonds or coordinated metal ions, large domains comprising more than 300 residues are expected to contain multiple hydrophobic cores.

Domains are genetically mobile units, and multidomain families are found throughout the three kingdoms (Archaea, Bacteria, and Eukarya). The majority of genomic proteins, 75% in unicellular organisms and more than 80% in metazoa, are multidomain proteins created as a result of gene duplication events (Apic *et al*., 2001). Genetic mechanisms influencing the layout of multidomain proteins include gross rearrangements such as inversions, translocations, deletions and duplications, homologous recombination, and slippage of DNA polymerase during replication (Bork *et al*., 1992). Although genetically conceivable, the transition from two single-domain proteins to a two-domain protein requires that both domains fold correctly and that they manage to bury a fraction of the previously solvent-exposed surface area in a newly generated interdomain surface, the size of which depends on the constraints imposed by the domain linker region and the scale of domain interaction.

Protein structure is intrinsically hierarchic in its internal organization. It progresses from secondary structure (*see* Article 76, **Secondary structure prediction**, Volume 7) elements at the lowest level, via supersecondary structures and domains to complete proteins and assemblies of proteins at the highest level. At the domain level, the connectivity of the polypeptide backbone between the domains appears to be less important, as the protein retains a stable structure irrespective of the sequential ordering of the domains. Moreover, evolution has led to various forms of domain arrangements across the protein sequence that can be classified by their connectivity (Das and Smith, 2000). These arrangements go beyond sequential permutations of complete domain structures and can affect the internal domain organization. Figure 1 displays the observed modes of connectivity between domains

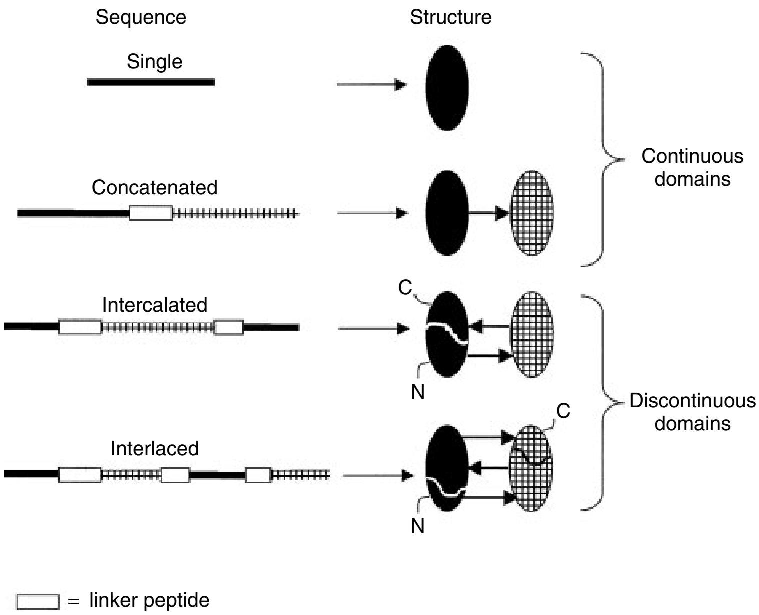

Figure 1 Schematic illustration of different types of backbone connectivity in multidomain protein structures (right) and their coding peptide sequences (left). Note that continuous domains are encoded by uninterrupted sequences, whereas discontinuous domain sequences show inserted sequence fragments

ordered by the degree of complexity. On the basis of their connectivity, domains can be divided into two main classes: continuous domains, where the associated coding sequence is an uninterrupted stretch of amino acids, and discontinuous domains, where the coding sequence is interrupted by subsequences encoding alternative structures, such as inserted domains. An example of a multidomain structure with a combination of continuous and discontinuous domains is the three-domain structure pyruvate kinase, a member of the phosphotransferase family, the structure and connectivity of which are given in Figure 2.

A protein module has been defined as a continuous domain structure that is structurally independent enough to serve as a modular plug-in to many multidomain proteins. Modules are believed to have spread largely by exon shuffling and are observed in many different multidomain proteins with permuted or altogether different domain combinations. The fact that modules often show the N- and C-termini in close proximity appears to facilitate their addition to other protein structures, since their insertion in loop regions would not require gross rearrangements.

A structurally viable mechanism for forming oligomeric domain assemblies is provided by domain swapping (Bennett *et al*., 1995). In domain swapping, a secondary or tertiary element of a monomeric protein is replaced by the same element of another protein. Domain swapping can range from secondary structure elements to whole structural domains in bringing together single-domain or multidomain

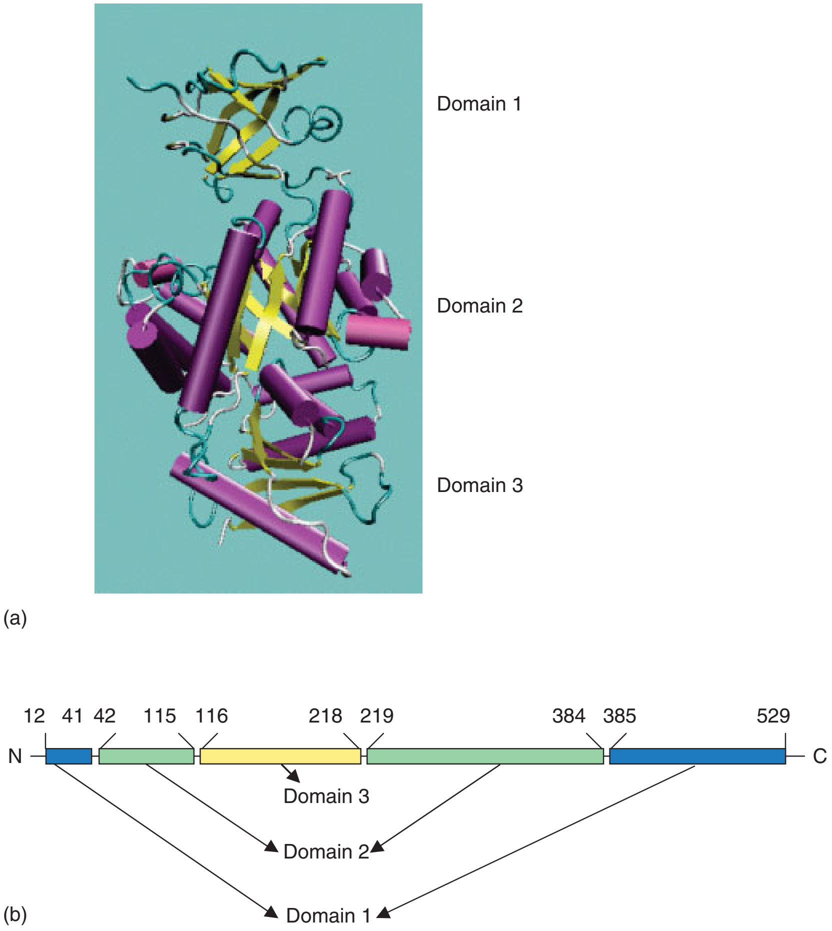

Figure 2 Pyruvate kinase structure and domain connectivity. (a) The structure shows three domains: domain 1 (discontinuous) is a β-barrel regulatory domain; domain 2 is a discontinuous α/β barrel catalytic substrate-binding domain; and domain 3 corresponds to a continuous α/β nucleotide-binding domain. (b) Schematic representation of the corresponding amino acid sequence, showing the segmental arrangement of the three domains. The intercalated and interlaced structures have N- and C-termini indicated (designated "N" and "C", respectively) for clarity

structures. It also represents a model of evolution for functional adaptation by oligomerization, for example, of oligomeric enzymes that have their active site at subunit interfaces (Heringa and Taylor, 1997).

2. Predicting domain boundaries in multidomain proteins

A number of structural classification methods have been developed to group the large number of protein domain folds deposited in the Protein Data Bank (PDB)

(*see* Article 71, **The Protein Data Bank (PDB) and the Worldwide PDB http://www.wwpdb.org**, Volume 7). The most widely used structural databases are CATH (Orengo *et al*., 1997), SCOP (Lo Conte *et al*., 2000), FSSP (Holm and Sander, 1996), and 3Dee (Siddiqui *et al*., 2001). Links to Web servers for these databases are provided in Table 1. For each database, a unique protocol is followed to classify the protein structures at the domain level. Since a common operational definition of a domain is that of a compact globular substructure with more interactions within itself than with the rest of the structure (Janin and Wodak, 1983), two characteristics are commonly exploited in boundary prediction methods: extent of isolation and compactness (Tsai and Nussinov, 1997). Measures of local compactness have been used in a number of recent domain-assignment methods (Holm and Sander, 1994; Islam *et al*., 1995; Sowdhamini and Blundell, 1995; Siddiqui and Barton, 1995; Nicols *et al*., 1995; Zehfus, 1997; Hinsen *et al*., 1999; Taylor, 1999; Xu *et al*., 2000; Siddiqui *et al*., 2001; Guo *et al*., 2003), albeit these approaches generally cannot handle discontinuous or closely interacting domains very well. As a result, Hadley and Jones 1999 observed discrepancies between assignments made by the above structural domain databases.

A large number of profile and HMM (hidden Markov model; *see* Article 98, **Hidden Markov models and neural networks**, Volume 8) methods are available to delineate the domain structure in a query sequence. These methods make use of

domain classifications in protein domain sequence databases, and use the deposited sequences of each domain family to derive a profile or HMM. Each profile or HMM is then used to scan the query sequence, after which the highest scoring ones are used to delineate the putative domains and their boundaries. Recent developments for these search techniques is the addition of contextual information such as co-occurrence of domains in a sequence (Coin *et al*., 2003) and the taxonomic distribution (Coin *et al*., 2004).

Although a very difficult task, some ab initio computational methods are also available for the prediction of domain boundaries from protein sequence information alone. The method SnapDRAGON (George and Heringa, 2002a) is primarily based on the hydrophobic collapse during folding and folds a 3D protein structure on the basis of the notion of conserved hydrophobicity and information from secondary structure prediction methods. The method takes as input a multiple alignment of the query sequence and a set of homologs, as well as the predicted secondary structure. It then builds 100 models of the protein structure, with each assigned domain boundaries using the aforementioned method of Taylor (1999). A final prediction of the domain boundaries is achieved by assessing the consistency of the domain boundaries over the 100 predicted folds and by determining statistically significant boundaries.

Domain boundary identification by comparative sequence analysis is performed by the method DOMAINATION (George and Heringa, 2002b), which is based on the homology search method PSI-BLAST (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7; Altschul *et al*., 1997) to identify homologs to a query sequence. The distribution of N- and C-terminal positions of the local alignments obtained by PSI-BLAST is used to identify putative domain boundaries by a process of chopping and joining domains and domain segments in an attempt to reconstruct the evolutionary loss and gain of domains. The method follows an iterative protocol of on-the-fly cutting and joining of domain fragments and subjecting newly formed fragments to PSI-BLAST. It is able to recognize continuous and discontinuous domains and increases the accuracy of PSI-BLAST by about 15%.

3. Domain fusion

Domains in multidomain structures are likely to have once existed as independent proteins, and many domains in eukaryotic multidomain proteins can be found as independent proteins in prokaryotes (Davidson *et al*., 1993). As an example of gene fusion, vertebrates have a multienzyme protein (GARs-AIRs-GARt) comprising the enzymes glycinamide ribonucleotide synthetase (GARs), aminoimidazole ribonucleotide synthetase (AIRs), and GAR transformylase (GARt) 1. In insects, the corresponding polypeptide encodes the four-domain structure GARs-(AIRs)2-GARt. However, GARs-AIRs is encoded separately from GARt in yeast, and in bacteria, each domain is encoded separately (Henikoff *et al*., 1997).

Marcotte *et al*. (1999) introduced the "Rosetta Stone" computational method for inferring protein function and interactions from genome sequences on the basis of the observation that some pairs of interacting proteins have homologs in another

organism fused into a single protein chain. A comparison of sequence homologs from multiple organisms can reveal these fused sequences, which are called Rosetta Stone sequences because the existence of these multidomain proteins implies the putative interactions between the separate protein pairs in other organisms.

Another genomic method to predict domain function is phylogenetic profiling (Pellegrini *et al*., 1999). The method checks for simultaneous presence or absence of pairs of genes across a wide spectrum of genomes, and thereby reveals sets of proteins that are likely to have coevolved, and thus can be expected to act in the same cellular process.

The protein phylogenetic profiling and the Rosetta Stone methods have been very useful in predicting the function of large numbers of genes without experimental functional annotation.

4. Domain evolution and gene duplication

The evolution and spread of domains through different protein families is likely to be the result of *gene duplication*, leading to one or more paralogous genes. After such duplication events, the selection pressure becomes less for the paralogous copies of the gene, so that these are freer to manufacture adaptive functions over time. For more recently evolved protein domains, a correspondence between the sequential boundaries of exons and those of protein domains is observed. It is therefore believed that *exon shuffling* during evolution has enabled organisms to develop new proteins with new functions by the addition of exons from other parts of the genome that form new domains as part of an existing protein.

A multidomain architecture offers the potential of reuse through domain repeats (*see* Article 33, **Protein repeats**, Volume 7). Domain duplication is essential for the formation of the active sites of enzymes such as in the aspartic and serine proteinases, porphobilinogen deaminase or the binding sites of transport proteins such as lactoferrin, transferrin, and sulfate-binding protein. Domain repeats also result in duplication of active sites or binding sites such as the calcium binding sites in calmodulin or the nine DNA-binding zinc fingers of the transcription factor TFIIID.

Recent methods to delineate repeats in protein sequences are RADAR (Heger and Holm, 2000), REPRO (George and Heringa, 2000; Romein *et al*., 2003), and TRUST (Szklarczyk and Heringa, 2004). Taylor *et al*. (2002) devised a method based on Fourier analysis to automatically recognize repeated substructures in protein structures.

5. Nonorthologous displacement

An increasing number of cases are identified for nonorthologous displacement (Koonin *et al*., 1996), where enzymes carrying out an identical function in different organisms belong to entirely different protein families, and, thus, are not expected to show any sequence similarity. Examples of nonorthologous displacement include ornithine decarboxylase in *E. coli* and *S. serevisiae*, where the isozymes speF

and speC are responsible for this function in *E. coli* and share the same structure comprising three domains (ornithine decarboxylase N-terminal “wing” domain, PLP-dependent transferase, and ornithine decarboxylase C-terminal domain). The corresponding enzyme spe1 in *S. cerevisiae* is a two-domain protein with entirely different domain structures (PLP-binding barrel and alanine racemase-like domain). A problem with nonorthologous displacement is that it cannot be recognized by sequence comparison methods, which are aimed at recognizing divergent evolution by mutation and insertions/deletions, including changes of gene structure by gene fusion or fission. However, the techniques are not able to trace evolutionary cases of horizontal gene transfer or functional displacement of one gene by another one within a genome.

Suppose that a set of proteins is studied that correspond to a linear metabolic pathway, and that all proteins are found for a given organism, except for one corresponding to an intermediate step. It can then be expected that the missing activity is performed by some hitherto undetected protein, in which case sequence comparison techniques can lead to the identification of the missing protein by a homology search using a homologous domain sequence in another genome that has the appropriate functional annotation. In the absence of any putative homolog, nonorthologous gene displacement could be suspected, in which case direct sequence analysis is of no use. However, functional ontologies, such as GO (*see* Article 82, **The Gene Ontology project**, Volume 8; Ashburner *et al*., 2000), can aid the process in that various nonorthologous sequences can be identified using a GO functional descriptor. This leads to a direct candidate whenever a protein domain is identified in the target genome. Otherwise, if the ontology identifies a putative nonorthologous gene with the desired function in another genome, a homology search (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7) using the latter gene can reveal putative nonorthologous genes for the intermediate metabolic step in the query organism.

In the case of a prokaryotic organism, the fact that gene sequences in close proximity in the genome tend to be functionally related can be exploited. Given a confirmed protein domain sequence associated with the above metabolic pathway, the neighborhood of its homologs in complete prokaryotic genomes can be analyzed using the STRING server (Snel *et al*., 2000). The latter server has been used, for example, for the reannotation of the *Mycoplasma pneumoniae* genome (Dandekar, *et al*., 2000).

6. Homology regions

As a result of a homology search operation, for example, by using the program PSI-BLAST (Altschul *et al*., 1997; *see also* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7), regions with significant similarity between otherwise unrelated proteins in different species can abound. Such so-called homology regions can be sustained within different sequence contexts, and often add a specific functionality to their constituent proteins. In some cases, the function of regional homology domains can be inferred by comparing the properties of the host proteins, when experimental functional annotation is available.

However, the detection of these domains in uncharacterized sequences can also provide valuable clues for the protein's function. In other cases where the biological role of a local homology domain is not known, the delineation and comparison of these regions might still be useful, for example, for finding conserved residues as targets for mutagenesis or for structural studies.

7. Assessing functional specificity of domain families

Predicting or assessing the functional specificity of a given domain sequence is possible when a set of homologs is available for a query sequence, and the homologs are suspected to have a roughly identical function but with subtle variations (e.g., dehydrogenase domain structures acting on different substrates). Insight can then be gained by aligning the members of the family and deriving a phylogenetic tree. If the family is organized into a tree that correlates well with the functions described (or derived) for the proteins, then one can draw relatively reliable conclusions regarding the query's function. If the query falls into a clear subgroup of the tree, one can assume that as a function of the branch. If, however, the functional annotation of the branch holding the query is heterogeneous, or the query falls in between two branches, then one should assume a less-specific description in accordance with the neighboring branches (e.g., "alcohol dehydrogenase"), or resort to the generic functional description of the whole family (e.g., "dehydrogenase").

The transfer of function from one protein to another should only be done when the protein sequences match over their total lengths in the pairwise sequence alignment, without any large unaligned sequence fragments that might correspond to an additional domain. If some fragments do not align, one has to carefully check whether the function that is transferred really corresponds to the part that is common. The use of domain databases and methods for domain identification (*vide supra*) can be of great help at this point.

If a query sequence contains a domain that is not matched in the pairwise alignment, this should be noted. Conversely, if the protein used as source of the annotation contains an unmatched domain, the annotation should just state the presence of the domain(s) of the query without transferal of the complete functional description of the source.

8. Protein sequence clustering

Protein sequence cluster databases group related proteins together and are derived automatically from protein sequence databases using different clustering algorithms.

Each database uses a different clustering algorithm aimed at grouping the sequences generally in homologous families and superfamilies. Assignment of a query sequence without annotation to any of the clusters can provide valuable clues about the protein's function. Since they are derived automatically from protein sequence databases without manual crafting and validation of family discriminators, these databases are relatively comprehensive, although the biological relevance of clusters can be ambiguous and can sometimes be an artifact of particular thresholds.

Multidomain protein sequences are a particular source of error in that the clustering algorithm can establish a link between two sequences A and B on the basis of a particular domain, while a third sequence C might be linked to sequence B on the basis of another domain sequence. If unchecked, this would lead to an incorrect clustering of sequences A, B, and C. Table 1 provides a number of links to websites of protein sequence clustering databases.

8.1. Interaction domains

A large and growing body of evidence suggests that proteins involved in the regulation of cellular events such as the cell cycle, signal transduction, protein trafficking, targeted proteolysis, cytoskeletal organization, and gene expression are typically multidomain proteins comprising a catalytic domain and one or more interaction domains. Interaction domains induce the interaction of signaling polypeptides and specific multiprotein complexes. For example, they can couple a cell surface receptor to an intracellular biochemical pathway that controls the cellular responses to an external signal. Interaction domains can be involved in a series of protein–protein interactions, designed to localize signaling proteins to appropriate subcellular locations or to determine the enzyme specificity. A well-studied example is the family of protein kinases in relation to their substrates. Typically, protein–protein interaction domains are relatively small and independently folding modules of 35–150 amino acids that are able to fold in isolation from their host proteins while retaining their intrinsic ability to bind their physiological partners. Their N- and C-termini are usually close together in space, while their ligand-binding surface lies on the opposite face of the domain. This arrangement facilitates their evolutionary use as a modular plug-in since it allows the domain to be easily inserted into a host protein while projecting its ligand-binding site to contact other polypeptides.

Protein–protein interaction domains can be clustered into separate families, based either on their sequence or ligand-binding properties. Interaction domains are often used repeatedly by a large number of multidomain proteins that display very different domain structures, where they mediate a particular type of molecular recognition.

1. An important class of interaction domains recognizes peptides that have been posttranslationally modified. These modifications include phosphorylation, acetylation, or methylation. The dynamic control of cellular behavior exerted by covalent protein modifications, therefore, appears largely mediated by interaction domains that regulate the associations of signaling protein cascades.
   (a) Phosphorylation:
      (i) An important member of this class is the SH2 domain, which is anticipated to be encoded in the human genome at least 120 times. A large number of cytoplasmic proteins contain one or two SH2 domains that directly recognize phosphotyrosine-containing motifs that are found, for example, on surfaces of activated receptors for cytokines, growth factors, and antigens. SH2 domains all recognize phosphotyrosines, but have different preferences for amino acids immediately following the

phosphorylated residue, allowing a degree of specificity in signaling by tyrosine kinases.

(ii) Phosphotyrosine-containing motifs are also recognized by the PTB domain, a very different structure than the SH2 domain. PTB domains are found as constituents of binding proteins such as the IRS-1 substrate of the insulin receptor.

(iii) Phosphoserine and phosphothreonine motifs are targeted by a growing family of interaction domains, including FHA domains, 14-3-3 proteins, and WD40-repeat domains. Each of the subfamilies and proteins contained therein bind specific phosphoserine/threonine motifs, and thus mediate the biological activities of protein-serine/threonine kinases.

(b) In addition to phosphorylation, acetylation and methylation have recently been implicated in inducing modular protein–protein interactions. For example, acetylation or methylation of lysine residues on the surfaces of histone structures, respectively, create effective binding sites for Bromo and Chromo domain constituents of multidomain proteins involved in chromatin remodeling.

2. A large group of interaction domains bind proline-rich motifs, including SH3, WW, and EVH1 domains. The complexes that are recognized by these domains are therefore not dependent on posttranslational modifications, and hence are more stable partners than those that, for example, need to be phosporylated to enable binding by SH2 domains. SH3 domains interact with a large number of different domain types and are therefore referred to as “promiscuous” domains.
3. PDZ domains bind the C-termini of their interaction partner domains, ion channels, and receptors in a fashion that appears important for the localization of their targets to particular subcellular sites, as well as for downstream signaling. In addition to binding short C-terminal peptide motifs, PDZ domains can form heterodimers.
4. In addition to binding specific peptide motifs, a growing number of interaction modules are known to recognize a variety of phospholipids, particularly phosphoinositides (PI). For example, PH domains are constituents of lipid kinases and phosphatases, where they affect cellular functioning by binding promiscuously to either the phosphoinositide PI-4,5-P2 or PI-3,4,5-P3. On the basis of their phospholipid-binding, PH domains can localize signaling proteins to specific subregions of the plasma membrane, where they regulate the enzymatic activities of their host proteins.

A predominant feature of interaction domains is their apparent versatility. Though PTB domains were originally discovered on the basis of their ability to bind phosphorylated tyrosines within Asn-Pro-X-Tyr (NPXY) motifs, many PTB domains appear to be able also to recognize unphosphorylated NPXY-related peptides. It, therefore, appears that PTB domains originally evolved to bind unphosphorylated peptides, but have subsequently developed a capacity to recognize phosphotyrosine in relatively few specific cases. Furthermore, some individual PTB domains, for example, those within the FRS-2 and Numb proteins, have evolved to recognize two quite different peptide ligands.

Although many interaction domains bind very different substrates, a number of them have similar tertiary structures, such as, for example, the PTB, EVH1, and PH domains, which, respectively, recognize phosphotyrosine-containing peptide motifs, proline-rich peptides, and phospholipids (*vide supra*). The PTB/PH/EVH1 fold is shared by other types of interaction domains as well. It seems therefore that this domain fold provides a stable framework that can be used for modulating very many different intermolecular interactions. On the other hand, many signaling proteins contain a number of different interaction domains to yield a multidomain protein that can mediate multiple protein–protein and protein–phospholipid interactions. This modular organization of signaling proteins can target proteins to the appropriate site within the cell, and direct binding to cell surface receptors and downstream targets.

A number of bioinformatics approaches have been developed for the prediction of protein–protein interactions based on the correspondence between the phylogenetic trees of interacting proteins (Goh *et al*., 2000; Pazos and Valencia, 2001) and detection of correlated mutations between pairs of proteins (Pollock and Taylor, 1997; Pazos *et al*., 1997; Pollock *et al*., 1999).

9. Spacer domains and domain linkers

A number of protein domains are thought to have a purely structural role, allowing functional domains to be advantageously situated, or providing the overall protein with the necessary flexibility. It must be kept in mind that a domain may be considered to have a purely structural role simply because knowledge about its true function is missing. The immunoglobulin (Ig) family provides examples of this, as the Ig constant heavy 1 and 2 domains and the Ig constant light domain act as "spacer" domains to allow the Ig variable light and heavy domains to function optimally.

Multifunctional enzymes are generally composed of a number of discrete domains that are connected by interdomain linkers. A number of site-directed mutagenesis experiments have shown that linkers play a crucial role in the enzymatic activity of multidomain complexes (George and Heringa, 2003). In general, mutating or altering the length of linkers has been shown to affect protein stability, folding rates, and domain–domain orientation. The linkers provide dynamic structural bridges for the movement of ligands across the modules. Many linkers act as rigid spacers separating two domains, and provide a scaffold to prevent unfavorable interactions between folding domains. George and Heringa (2003) found the two main types of linker in natural proteins: helical linkers and nonhelical linkers. Helical linkers derive their rigidity from their helical conformation, while nonhelical linkers are rich in proline residues, which also leads to structural rigidity. They should be flexible, keeping domains apart while allowing them to move as part of their catalytic function. Linkers should, furthermore, be invulnerable to host proteases, as they are often the targets for degradation.

10. Domain movements

Domain motions are important for a large repertoire of functions including ligand binding, catalysis, regulation, formation of protein assemblies, and transport of

metabolites (Gerstein *et al*., 1994). Often, the binding site is situated at the interface of a pair of domains in the "closed" conformation, corresponding to the inactive form of the associated multidomain enzyme, while the "open" conformation of the domains exposes the binding site and, thus, provides the active form of the enzyme. Domain motions are often responsible for the mechanism of "induced fit" observed in protein–protein recognition.

Protein flexibility often corresponds to large relative movements of domains. In aspartic proteinases, for example, the two main domains forming the lobes of the structure show large relative shifts that are crucial for the activity of the constituent enzyme (Sali *et al*., 1992). Another example is the so-called swiveling domain in pyruvate phosphate dikinase (Herzberg *et al*., 1996), which brings an intermediate enzymatic product over about 45 Å from the active site of one domain to that of another. Such movements have been determined by a conformational analysis of protein structures, where the identification of, for example, hinge axes and their corresponding rotation angles permits a useful representation of protein domain movements (Gerstein *et al*., 1994).

Three main mechanisms of domain movements are discernible (Gerstein *et al*., 1994):

1. *Intrinsic flexibility:* These movements lead to deformations of the domain structure. Several small movements in secondary structures have a cumulative effect. These motions are due to small changes in backbone torsion angles of strands and/or helices, kinks involving prolines in helices as in adenylate kinase (Gerstein *et al*., 1994), or interconversion of helix and extended conformations as in calmodulin (Ikura *et al*., 1992).
2. *Hinged domain movements:* Of special interest are hinge-bending movements, where rigid domains are connected by flexible joints that tether the domains and constrain their movement. Hinge-bending is believed to allow an induced fit of molecular surfaces in protein assembly and ligand docking. These movements are caused by rotations of a domain around a pivotal point, often afforded by a linker region in between domains that changes its conformation to allow the rotation. For example, to attain icosahedral symmetry, the S and P domains of tobacco bushy stunt virus perform hinge movement mainly by dihedral angle changes in the peptide that forms a linker between the two domains (Olsen *et al*., 1983). In lactoferrin, the open and closed forms of the two domains involve a 53° rotation, which is achieved by conformational changes within two strands that connect the protein's two domains (Jameson *et al*., 1998).
3. *Ball-and-socket motion:* The variable (light and heavy chain) domains of antibodies rotate about 50° with respect to the constant (light and heavy chain) domains by means of a combination of hinge and shear motions (Lesk and Chothia, 1988).

The method HINGEFIND (Wriggers and Schulten, 1997) identifies domain movements and characterizes and visualizes the effective rotation axes (hinges). The program compares a pair of known structures (e.g., two different crystal structures of a protein or the results of molecular dynamics or Monte Carlo simulations) and partitions the protein with a prespecified tolerance in preserved subdomains.

It then determines effective rotation axes that characterize the domain movements with respect to the reference domain ("rigid core"). Hayward and Berendsen (1998) have developed a method to analyze comparative domain movements over larger sets of structures.

11. Conclusion

The analysis and prediction methods that elucidate the evolutionary development and function of domains and multidomain complexes have recently been enriched by the integration of genomic and dynamic contextual information. Many successes are to be derived from the ongoing developments in spawning an integration web between genomics, phylogenetic, sequence, structure, structural dynamics, and function data. This will shed more light on the evolution of the structural and functional versatility of protein domains, which will benefit biotechnical and biomedical applications.

Specialist Review

Complexity in biological structures and systems

Arthur M. Lesk
The Pennsylvania State University, University Park, PA, USA

1. Introduction

Complexity is a concept that we encounter in our daily lives, but generally we can get along without needing to define it precisely. But, how well do we really understand complexity, and allied concepts including entropy, randomness, predictability, and chaos? What are the relationships among them? And how can they be used to illuminate biology?

No one doubts that life is complex. Until recently, the response of biological scientists has been to carve off pieces that might be simpler to deal with by themselves. The observation by the Buchners of enzymatic activity in yeast cell extracts initiated an exhaustive program of isolation and purification of proteins. The activity of a purified enzyme is not without complexity, but the approach of classical biochemistry was to simplify. Now we hope to face complexity head-on (for additional reading, see Adam, 2002; Cramer and Loewus, 1993; Colosimo, 1997; Colosimo, 2004).

How to proceed? Interrogating our naive and colloquial concepts of words is a starting point, if only to expose our prejudices. However, it ultimately becomes unproductive, and must be abandoned when it does. What formal theory can we call upon as an alternative?

2. Complexity of sequences

Perhaps the simplest complex object in biology is a sequence. We have heard of random sequences, and probably have the general idea that the more random the sequence the more complex it is. Genomic sequences contain "low-complexity" regions – are these regions more or less random than a protein-coding region? How can such properties of sequences be measured?

Given a sequence of characters $x_1, x_2, x_3, \ldots$ with each x_i chosen from an alphabet $\mathcal{A}$, what controls the amount of information needed to identify individual characters? If the alphabet $\mathcal{A}$ is very large, and if the x_i are evenly distributed, more information is needed than if $\mathcal{A}$ is small or the distribution of the x_i is highly skewed.

For example, genomic sequences contain characters A, T, G, and C. To identify each symbol, it suffices to ask two "yes-or-no" questions:

- Question 1: Is it a purine (or a pyrimidine)?
- Question 2: Is it 6-keto (or 6-amino)?

Representing yes = 1 and no = 0, the answer to each "yes-or-no" question provides 1 binary digit, or *1 bit* of information. In principle, we could encode each nucleotide as a two-bit binary string. In practice, we encode each nucleotide as a 1-byte (8-bit) character. This is more than necessary: with 1 byte we can encode the entire English alphabet plus special symbols of the ASCII character set.

It is reasonable that a string containing text plus special symbols is more complex than a genomic sequence of the same length containing only A, T, G, and C. As we shall see, allocation of unnecessarily generous space per character in the 1 byte/nucleotide representation allows genomic sequences to be compressed, and they can, in principle, be compressed more effectively than a string of ordinary text. Here is a hint of a relationship between compressibility and complexity, a theme we shall develop.

Questions about the required length of representations appear in the genetic code itself. How many nucleotides are required to encode 20 amino acids? Two are not enough: an alphabet of 4 nucleotides provides only 16 dinucleotides. If all amino acids are to require the same number of nucleotides, there must be at least three nucleotides per codon, as observed.

How can these informal considerations be made quantitative? In 1948, C. E. Shannon introduced the concept of *entropy* in information theory, in his analysis of signal transmission. Suppose the probability of each symbol x_i is p_i, with $0 \leq p_i \leq 1$ and $\sum_i p_i = 1$. Shannon's measure of entropy is:

$$H = -\sum_i p_i \log_2 p_i \tag{1}$$

The entropy can be interpreted as the minimum average number of bits per symbol required to transmit the sequence. For a genomic sequence with equimolar base composition, $p_A = p_T = p_G = p_C = 0.25$, $H = 2$. This recovers our informal result that each symbol requires two bits, or answers to two "yes-or-no" questions. For a sequence limited to two equiprobable characters A and T: $p_A = p_T = 0.5$, $H = -[0.5 \log_2 0.5 + 0.5 \log_2 0.5] = 1$. This makes sense because, knowing that the only choices are A and T, we can decide which base it is with *one* 'yes-or-no' question. We could encode A = 1 and T = 0, in one bit.

Suppose instead that a sequence has the skewed nucleotide composition: $p_A = p_T = 0.42$, and $p_G = p_C = 0.08$. Then

$$H = -[0.42 \log_2 0.42 + 0.42 \log_2 0.42 + 0.08 \log_2 0.08 + 0.08 \log_2 0.08] = 1.63 \tag{2}$$

What is the significance of the fact that $H = 1.63$ is less than 2? The uncertainty in each transmitted symbol is not complete – A and T are more likely than G and C. In principle, we can use this to improve the coding efficiency.

The Morse code for telegraphy took advantage of unequal letter distribution frequencies to encode common letters (in English) with short sequences and uncommon letters with longer ones (for instance, E = dot and J = dot-dash-dash-dash). Huffman's (1952) general method assigns length-optimal codes to symbols from their relative probabilities.

It would be difficult to devise a Morse code for nucleotides because the fact that we can easily encode them with no more than two bits does not give us much room to play with: we cannot subdivide a bit. However, consider encoding a genome sequence as a succession of trinucleotides, assuming no bias in trinucleotide frequencies other than that expected from the mononucleotide frequencies. That is, if $p_{\mathrm{A}} = 0.42$ and $p_{\mathrm{C}} = 0.08$, $p_{\mathrm{ACC}} = 0.41 \times 0.08 \times 0.08$. There are 64 trinucleotides to encode. Six bits per triplet obviously suffice, but for the skewed distribution $p_{\mathrm{A}} = p_{\mathrm{T}} = 0.42$, $p_{\mathrm{G}} = p_{\mathrm{C}} = 0.08$, $H = 4.9$. We could encode the sequence using 5 bits per trinucleotide instead of 6 (a good exercise for the reader).

It is possible to calculate entropies of genome sequences, and to use the entropy computed, over a sliding window, a window to detect low-complexity regions. In the human genome, these include simple repeats, or microsatellites, or regions of highly skewed nucleotide composition such as AT-rich or GC-rich regions, or polypurine or polypyrimidine tracts.

Conversely, it is observed that the distribution of oligonucleotides (dinucleotides, triplets, etc.) is uneven. Therefore, an encoding of a genetic sequence based on oligonucleotides could be shorter than an encoding of individual bases. It might also reveal biologically significant patterns; for instance, codon usage patterns in protein-coding regions. Some algorithms for gene identification make use of biases, in coding regions, of hexanucleotide frequencies.

The genetic code does not achieve theoretical coding efficiency, producing instead redundancy in the form of synonymous codons. (There does not seem to be selection for reduction in size of nonviral genomes.) The redundancy in the genetic code is utilized in evolution. Many single-nucleotide polymorphisms are silent, giving the code a certain error tolerance. Conservative mutations allow proteins to evolve with small nonlethal changes that, cumulatively, achieve large changes in structure and function.

In signal processing, extra coding bits can be used for error detection or even correction. In biology, the redundancy in having two copies of the genetic information in two strands of DNA is used to detect and correct errors in replication and translation, and to repair DNA damage.

Shannon entropy is related to the thermodynamic entropy by multiplying by Boltzmann's constant $k = 1.3807 \times 10^{-23}\ \mathrm{J \cdot K^{-1}}$ to give the statistical-mechanical equation:

$$S = -k \sum_{i} p_i \ln p_i \tag{3}$$

where the p_i are the probabilities of states of individual components of a physical system, such as the particles in a gas. The relationship between information theory and statistical mechanics has been explored by physicists, including J. C. Maxwell and L. Szilard, in their discussions of "Maxwell's demon"; and by E. T. Jaynes (see Rosenkrantz, 1983).

3. Randomness of sequences

The Shannon entropy of sequences is related to their randomness, another concept we use in everyday life without worrying too much about exactly what it means. Randomness has been made precise in independent work by A. N. Kolmogorov, R. Solomonoff, and G. Chaitin (Li and Vitanyi, 1997).

Kolmogorov defined the randomness of a sequence of numbers as *the length of the shortest computer program that can reproduce the sequence*. The sequence 0, 0, 0, 0, 0, 0, 0 . . . is far from random, as it is the output of the short program:

Step 1: print 0.
Step 2: go back to step 1.

Periodic sequences, such as:

Monday, Tuesday, Wednesday, Thursday, Friday, Saturday, Sunday, Monday, . . . are also nonrandom. In contrast, a truly random sequence has no description shorter than the sequence itself.

Kolmogorov's definition distinguishes truly random sequences from pseudorandom sequences. A pseudorandom sequence is a sequence of numbers generated by some program; with a distribution similar to that of a random sequence, with no obvious biases or correlations. Pseudorandom numbers suffice for many applications, such as Monte Carlo calculations. However, the random-number generator is a shorter program to generate the sequence than the sequence itself (provided that we generate a long enough sequence). The Kolmogorov randomness of a pseudorandom sequence is therefore relatively low.

4. The relationship between compressibility and complexity of sequences

One way to shorten the specification of a sequence is to compress it. We all compress our files, using, for instance, gzip (Ziv and Lempel, 1977; Welch, 1984). If a sequence is truly random, in the sense of Kolmogorov, it cannot be compressed, by gzip or any other method. Although nonrandom sequences *can* be compressed, particular algorithms such as gzip do not give optimal compressions of all data sets. Indeed, the Kolmogorov definition of randomness does not specify the compression method. Rather it is defined in terms of *decompression* algorithms, that (re)generate the sequence.

5. The relationship between predictability and compressibility

One basic principle of compression algorithms is that if you can predict what is coming next, you can compress a description. The reason that the sequences 0, 0, 0, . . . and Monday, Tuesday, Wednesday, . . . are so compressible is that it is simple to specify the successor of any element. Even sequences without rules stating explicitly what the next element is can be compressed, if some indications

are available. It is not necessary that the indicators be supplied "up-front", as they can be for sequences such as 0, 0, 0, ... and Monday, Tuesday, Wednesday, ... The rules and statistics for predicting a successor can be probabilistic rather than unambiguous, and can be generated "on the fly" from incoming data.

6. The relationship between predictability and complexity

These considerations suggest a general idea that *the harder it is to predict the contents of a data set from a subset of the data, the more complex the data set is.* This proves to be a most useful guiding principle in analyzing the nature of the complexity of new types of data, and if there is any single take-home message from this article it is the significance of the relationship between predictablility and complexity. In facing a new type of object, and trying to devise a measure of complexity for it, ask yourself: knowing part of the object, how well can I predict the rest of it?

The considerations we have discussed describe the complexity of the *structures* of objects, specifically character strings. But, for biology, we are also interested in complexity of *processes.*

7. Static and dynamic complexity

Complexity has many dimensions, and one of them is time. If we could define and measure the static complexity of a system, that would provide an approach to dynamic complexity: we could ask how the static complexity is changing with time. Such changes appear to be governed by general rules, such as the laws of thermodynamics.

Because living things are dynamic, we must consider complexity of processes. One approach to complexity of dynamics appeals to physics: biological molecules are systems of particles. They follow the laws of dynamics, and usually classical Newtonian mechanics is adequate. We could define and describe the trajectories of the particles, and use the results to analyze the complexity. From the point of view of Kolmogorov, the initial positions and velocities of the particles, the forces between them, and Newton's laws of motion, together provide a concise description of dynamics of the system. However, even within the framework of classical dynamics, this can break down in chaotic states. In these states, very small changes in the initial conditions lead to very large changes in subsequent trajectories. Prediction of the dynamics requires very precise statement of the initial conditions, and very precise knowledge of the forces. Specification of the information required to describe the dynamics cannot, in these cases, be concise. Chaos is an extreme form of dynamic complexity.

Given the difficulty of analyzing the complexity of dynamical systems, how can we approach this topic? Perhaps the best-developed area of analysis of complexity of processes is in studies of complexities of computational problems.

The question of the limits to efficiency of computations is now often presented in terms of the technical problem of writing code that can be pushed to solve larger and larger problems. However, historically it emerged from the attempts by Hilbert

to axiomatize all of mathematics, and by Russell and Whitehead to automate the process of deriving the consequences of axioms; through Gödel's showing the futility of these efforts; and on through von Neumann and Turing's early theories of programs (for history and perspective, see Hartmanis, 1989; Sipser, 1992; Papadimitriou, 1997 and Cook, 2003. For modern textbook treatments see Garey and Johnson, 1979; Papadimitriou, 1994 and Hopcroft *et al*., 2000).

8. Computational complexity

Computational complexity is relevant to our subject for two reasons. One is that it is in computer science that ideas of complexity have been made most precise. The ideas that have emerged give us tools for deciding whether we understand the systems with which we deal. Papadimitriou (1997) noted the belief that "complexity must be the manifestation of mathematical poverty, lack of structure". Many of us work in the hope that this might be modified to: ... *apparent* complexity must be the *remediable* manifestation of poverty of mathematical understanding, lack of *appreciation* of underlying principles of structure. Indeed, some problems even in computer science turned out to be less complex than they originally appeared.

The second reason is that if we, as computational biologists, consider undertaking some calculation, what we propose must be feasible. In this context, Papadimitriou also mentioned "the thesis that 'polynomial worst-case time' is a plausible and productive mathematical surrogate of the empirical concept of 'practically solvable computational problem' ".

An algorithm in computer science defines a process for solving a problem. Some algorithms have closed forms: an example is the algorithm for solving the linear equation $x - a = b$: **Return** $\mathbf{x} = \mathbf{b} + \mathbf{a}$. However, most algorithms are iterative, and compute a sequence of intermediate results during their operation. Usually, the larger the data set to which the algorithm is applied, the longer the execution time required. In computer science, the measure of the complexity of a problem is the relationship between execution time and problem size, as the problem size grows larger and larger, for optimal algorithms.

Here is a simple example:

> *Given a list of N unequal numbers, sorted in increasing order, and a probe number that appears in the list, determine the position at which it appears.*

A simple approach is *sequential search:* Check the elements in order, and stop when you hit the match. (Note that this algorithm would work equally well for unsorted as for sorted lists.) On an average, sequential search will find the answer after $\sim N/2$ comparisons. The execution time of a program based on this algorithm is therefore expected to be proportional to N. This is called the *order* of the algorithm, $\mathcal{O}(N)$ (read "Oh-N"). We do not distinguish $\mathcal{O}(N)$ and $\mathcal{O}(N/2)$. Clever coding of an algorithm might speed up execution time by a factor of 2, but will not change an $\mathcal{O}(N/2)$ algorithm to an $\mathcal{O}(\log N)$ one. We want to characterize the behavior of the algorithm, not the implementation.

Does this *algorithm,* with execution time increasing as $\mathcal{O}(N)$, adequately characterize the *problem?*

No, because there are better algorithms that solve the same problem. A more clever approach is to compare the value of the submitted number with the number in the middle of the list, element $M = N/2$ (in integer arithmetic). If the target number is equal to element M, report M and stop. If the target number is larger than element M, throw away the initial half of the list. If the target number is smaller than the element M, throw away the final half of the list. Then repeat these operations, on the part of the list that remains. This *binary search* algorithm will require no more than $\log_2 N$ steps. The execution time of a program based on it will scale as $\log_2 N$ as N grows large. Just as we did not care to distinguish between $\mathcal{O}(N)$ and $\mathcal{O}(N/2)$ in the case of the sequential search algorithm, we say that the binary search algorithm has order $\mathcal{O}(\log N)$.

For very large N, binary search will be more efficient than sequential search. Of course, in special cases, sequential search would be better. (Suppose that B happens to = A(1).) We must ask for the asymptotic execution time of the algorithm that performs best for the *hardest* or *worst-case* data. That is the true test.

9. Classes P and NP

A problem that can be solved by an algorithm for which the running time is bounded (above) by a polynomial function $P_m(N) = a_m N^m + a_{m-1} N^{m-1} + \cdots a_0$ (with $a_m > 0$) of the problem size N – that is, the algorithm is $\mathcal{O}(P_m(N))$ – is said to be in *class P*. (Because for sufficiently large N the highest-power term will dominate, $\mathcal{O}(P_m(N))$ is equivalent to $\mathcal{O}(N^m)$.) Because $\mathcal{O}(\log N)$ is even *better* than $\mathcal{O}(N^m)$, our table-look-up problem, and other problems with $\mathcal{O}(\log N)$ optimal algorithms, are also in class P.

However, suppose that the optimal algorithm to solve a problem has order worse than polynomial – for instance exponential order $\mathcal{O}(10^N)$ – but that a *proposed* solution can be *checked* in polynomial time. Such a problem is said to be of *class NP*. (NP stands *not* for nonpolynomial, but for nondeterministic polynomial, referring to a different model for the computation. Do not worry about this distinction.)

Consider the problem of sorting a list of numbers. That is, given a series of N numbers: 2, 1, 7, 5, 8, 4, 3; an algorithm must produce as output the numbers rearranged from smallest to largest: 1, 2, 3, 4, 5, 7, 8. Whatever be the order of the optimal algorithm that solves the problem, an algorithm to *verify* that 1, 2, 3, 4, 5, 7, 8 is a solution (or that 1, 8, 7, 2, 4, 5, 3, is *not*) can run in linear time. Therefore, sorting a list of numbers into order is in class NP. (Sorting happens also to be in class P; sorting algorithms are known with order $\mathcal{O}(\log N)$.) Figure 1 shows the topology of complexity space, on the assumption that P is a proper subset of NP. (Whether or not this is true is an outstanding open problem in computer science; see below.)

Now, an obvious difficulty with the definition of class P is this: to define the complexity of a problem in terms of the complexity of an optimal algorithm, we must know the optimal algorithm. Some problems have been proved to be not in class P. But other problems may *appear* not to be in class P only until someone discovers a polynomial-time algorithm that solves them. The best currently known algorithm for any problem gives an *upper bound* to its computational complexity.

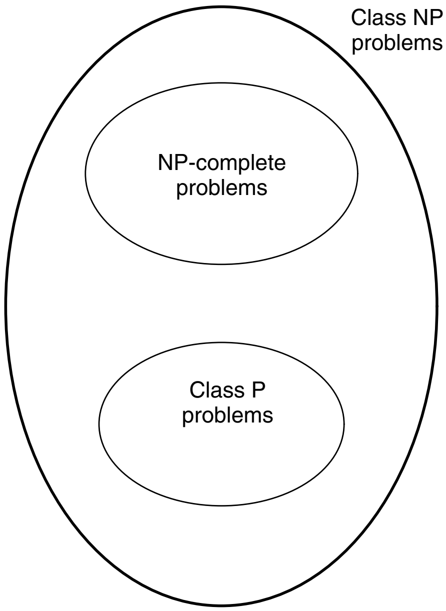

Figure 1 Computational problems can be in class P = problems for which algorithms of polynomial asymptotic order are known; NP-complete problems, a set of problems for which no algorithms of asymptotic polynomial-time order are known but which are reducible to one another in the sense that the discovery of an algorithm of asymptotic polynomial-time order for one of them (proving it to be of class P) would show that all NP-complete problems are of class P, or NP problems, for which all optimal algorithms are provably nonpolynomial. If it is found that P = NP, class P would be expanded to fill the entire class NP set

An example of such a reclassification was the discovery of a polynomial-time algorithm for linear programming (LP), the problem of maximizing or minimizing a linear function subject to linear equality and/or inequality constraints. It has a wide variety of important scientific and commercial applications. The *simplex algorithm* for solving LP problems was developed by G. Dantzig during World War II. This algorithm is quite effective in practice, but does not solve worst-case problems in polynomial time. (However, S. Smale showed that worst-case LP problems are sparse, accounting for the practical success of the simplex algorithm.)

For many years, we simply did not know whether linear programming is in class P or not. Then, in 1979, L. Khachyan presented a polynomial-time algorithm for LP. Although this resolved the theoretical problem – linear programming *is* in class P – it did not in itself provide software that would beat the simplex algorithm in the field. Five years later, N. Karmarkar devised a polynomial-time algorithm that did lead to effective programs.

10. NP-complete problems. Does P = NP?

Many NP problems have equivalent complexities, in the sense that if a polynomial algorithm were discovered for any one of them, it could be applied to solve others.

The set of *NP-complete problems* is the subset of NP problems, such that if we could solve any of them in polynomial time, we would be able to solve all of them in polynomial time. In other words, the discovery of a polynomial-time algorithm for *any* problem known to be NP-complete would cause the classes P and NP-complete in Figure 1 to coalesce. Are there *any* NP problems that are NOT in class P? This is the famous question: Does P = NP? A prize of $1 million is on offer for an answer.

Given that (1) many problems we wish to solve are NP-complete and (2) if we ask computer scientists for help with a problem, they are likely to say – typically with a sniff – "sorryit'sNPcompletegoodbye"; what is a poor biologist to do? In practice:

1. It is not always a vain hope that the worst-case behavior does not happen too often. (The simplex algorithm was successful for that reason.)
2. Often good approximations are available. Algorithms for some optimization problems often find an optimum or near-optimum quickly, and then spend a lot of time verifying optimality.

Theoretical barriers are genuine obstacles, but do not entirely exclude regions of practical feasibility and of genuine interest and utility.

11. Relevance of computational complexity to biological complexity

In applying ideas of computational complexity to biological systems, keep in mind that computational complexity describes the complexity of the *problem,* not the complexity of the device that solves it. Certainly, living systems function as computers. If I add 2 + 2 and get 4, I am doing a relatively simple computation; if I try to predict which horse will finish first in a race, I am doing a more complicated one. The regulatory activities that biological systems carry out are also optimization calculations. An example described by S. Brenner is the growth of bacteria in heavy water. Changing from H_2O to D_2O has the effect of changing the kinetic constants of many enzymatic reactions. After a relatively short period, cells readjust and resume activity and growth.

However, the theory of computational complexity is tied very closely to specific models of computations, which may not correspond to the computational architectures active in biology. The classic literature on computational complexity is based on computers that execute programs *sequentially*. Biological computers do lots of parallel processing. Exploration of generalizations of the classic results are a current research topic in computer science.

12. Computational complexity and sequence complexity

Let us revisit the two algorithms for determining the position of a number in a sorted list: simple sequential search and interval bisection. Given

a fixed finite sorted sequence of integers, each application of either algorithm to a test value generates a sequence of numbers as its search history. The search-history sequences generated by the two algorithms have different characteristics.

The search-history sequences generated by the sequential search method will have a distribution skewed to the earlier numbers in the list. The probability of checking the number in position i of the list is proportional to $N - i + 1$, where N is the length of the list. The search-history sequences generated by the binary search algorithm have a different distribution. We can calculate the entropies of these search-history sequences, and apply that and other tools to measuring their complexity as *sequences*. We find that the sequences generated by binary search are more complex than those generated by sequential search.

This provides an important connection between *complexity of structure* and *complexity of process*. We can collect the historical records of a process, and treat them as a structure. We can apply ideas of predictability and complexity of structures to these historical records, to give insight into the complexity of the process.

This relationship between the predictability of the course of a process and its complexity leads us naturally to reconsider the idea of chaos.

13. Predictability and chaos

The discovery of the laws of mechanics in the seventeenth century – Newton's *Principia* was published in 1687 – gave rise to the hope that the dynamics of the solar system (at least!) was predictable. Laplace wrote:

> *If we can imagine a consciousness great enough to know the exact locations and velocities of all the objects in the universe at the present instant, as well as all forces, then there could be no secrets from this consciousness. It could calculate anything about the past or future from the laws of cause and effect (quoted in Peitgen et al., 2004).*

Indeed, there were important implications about determinism in many-particle systems and even for free will in human behavior.

There were also questions of computability. How much information do we need, and how accurately do we need it, to predict the dynamics of the solar system? the weather? the universe? In some cases, the physical development of a system is relatively insensitive to the initial conditions. But in others, very small changes in initial conditions will lead to very different dynamic development of the system. Weather is an example: the meteorologist Lorenz gave a talk entitled: "Predictability: Does the flap of a butterfly's wings in Brazil set off a tornado in Texas?" Accurate prediction of the dynamics of such systems requires unachievably accurate knowledge of the initial conditions. Such systems exhibit chaotic dynamics. The courses of their development are unpredictable, and would remain unpredictable even if unlimited computational resources were available. Indeed, at the atomic level, Heisenberg's uncertainty principle killed off Laplace's hope of perfect determinism.

We can still make some predictions about the behavior of complicated systems. For instance, we can derive general macroscopic properties of a sample of a perfect

gas, such as $PV/T =$ constant, by averaging, even if we cannot follow the paths of the individual particles. Moreover, even chaotic (classical) systems are subject to Poincaré's recurrence principle: any system of particles held at fixed total energy will return arbitrarily closely to any set of initial molecular positions and velocities. What rescues the second law of thermodynamics is that the closer the reapproach demanded, the longer the time required, and the less probable the fluctuations required to achieve it.

In terms of complexity, chaotic dynamics is associated with unpredictability. However, chaotic behavior is not entirely incompatible with order and even the "spontaneous" generation of order. Many sequences associated with chaotic behavior have a *fractal* structure. This means that if an object is dissected, the parts have a structure similar to that of the whole (as well as to one another). Many beautiful fractal images have appeared (see, for example, Mandelbrot, 1982). This self-similarity at different scales implies that if we know part of such a structure we can predict a larger segment of it. This predictability should permit compressibility, and effectively reduce complexity. Indeed, fractal image compression is an effective tool for reducing the sizes of images (Barnsley, 1993).

Chaotic dynamics even sometimes produces stable states or approximations to stable states – called *attractors.* Some attractors are periodic and/or localized states. Others are *strange attractors,* which have a fractal structure. There have been examples of generation of order in model systems evolving "at the edge of chaos" (Kauffman, 1993).

We have now examined ideas of complexity for sequences, and for processes. Many biological phenomena can be described in terms of networks. Networks have both structure and dynamics. Can we apply the ideas developed to describe and analyze them?

14. Structure and complexity of networks

A network, or graph, is an abstraction of several types of biological phenomena in terms of a set of *nodes,* some or all pairs of which are joined by *edges* (see, *e.g.,* Strogatz, 2001). A *path* in a graph is a sequence of nodes $x, y, \ldots z$ with an edge between each successive pair of nodes. A graph containing a path between any two pairs of nodes is called *connected.*

The idea of a network is very general, including most if not all of the data types of modern biology. Sequences are networks: the nucleotides or amino acids are nodes, and edges connecting successive residues specify the order. The chemical bonding patterns of molecules are also networks, in which atoms are the nodes and bonds the edges. Later we shall see that abstract protein-folding patterns, defined in terms of contact patterns between helices and strands of sheet, are also representable by networks.

Microarray data on protein expression patterns or gene detection give rise to networks of relationships between genes. Although the output of a single chip is usually presented as a two-dimensional image, *topologically* these data are not two-dimensional. If two microarray patterns arise from comparable oligo sets – such as an experiment to determine the effect of a drug, or to determine the difference in

expression patterns between cancerous cells and normal tissue – the correspondence between the spots on the two arrays amounts to an alignment of a pair of sequences. An alignment is also a network, in which the nodes are the individual residues in the sequences, or the individual genes in the expression array, and the edges link both successive elements of individual sequences, and elements in different sequences or different arrays that are associated in the alignment.

Gene expression tables – matrices in which the rows correspond to different genes and the columns to different samples – are often analyzed by principal component analysis. This procedure derives, from the matrix, a sequence of eigenvalues. The extent to which the few largest eigenvalues account for the variability provides a measure of the complexity of the table.

15. Structures of networks

Typical networks in molecular biology include metabolic pathways, in which the nodes are metabolites and the edges are reactions that interconvert them; and gene regulation networks in which the nodes are genes and the edges are relationships between genes such that the expression of one gene activates or represses another.

Other familiar graphs include the World Wide Web, and networks of human acquaintance. "Six degrees of separation", the title of a play by John Guare, made into a film, refers to the assertion (attributed to Marconi) that if we form a graph with all human beings as the nodes, and connect by edges all pairs of people who know each other, then any two nodes are connected by a path of length ≤ 6.

The *density of connections* = the mean number of edges per vertex is an important characteristic of the structure of a network that governs its behavior. Nervous systems of higher animals achieve their power not only through having a large number of neurons but also by high degrees of connectivity.

In some networks, connectivities follow observable regularities. The World Wide Web is a network in which individual documents are nodes and hyperlinks are edges. The distribution of incoming and outgoing links follow power laws: $P(k) =$ probability of k edges $\sim k^{-q}$, where $q = 2.1$ for incoming links (other links that cite the node in question), and $q = 2.45$ for outgoing links (links cited by the node in question) (Albert and Barabási, 2002).

The density of connections is an important determinant of the dynamic behavior of a network. For instance, the interactions that spread disease among humans and/or animals form a network. As the density of connections increases, the system can exhibit a qualitative change in behavior, analogous to a phase change, from a situation in which the disease remains under control, to an epidemic spreading through an entire population.

16. "Small-world" networks

The Web exemplifies many networks that have the characteristics of high clustering and short path lengths. They contain relatively few nodes with large numbers of connections, called "hubs", and many nodes with few connections. These produce

short path lengths between all nodes. From this feature, they are called "small-world networks". Such networks tend to be fairly robust – staying connected after failure of random nodes. Failure of a hub would be disastrous but is unlikely, because there are few hubs. Hubs exist in biological networks also. Irizarry *et al*. (2005) suggest that regulatory networks of genomes may be partitioned into self-contained modules.

Many networks, notably the World Wide Web, are continuously adding nodes. The connectivity distribution tends to remain fairly constant as the network grows. These are called 'scale-free' networks (see Albert and Barabási, 2002; Barabási, 2003).

17. Robustness of networks

Biological systems need to be robust, both for survival of individuals under stress and for the plasticity required for evolution. In yeast, for example, single gene knockouts of over 80% of the ∼6200 open reading frames are survivable injuries.

In principle, networks can achieve robustness through redundancy. Wagner (2004) distinguished:

1. *Substitutional redundancy*: If two proteins are both capable of a job, knock out one and the other takes over. For example, it was found during attempts to develop mouse models for diabetes that mice and rats (but not humans) have two similar but nonallelic insulin genes. Substitutional redundancy requires equivalence not only of function but of control of expression. In the mouse, knocking out either insulin gene leads to compensatory increased expression of the other, and produces a normal phenotype. Such equivalent expression patterns are more probable among duplicated genes than among unrelated ones with equivalent functions.

2. *Distributed redundancy*: The same effect is achieved through different routes. In normal *E. coli*, approximately $\frac{2}{3}$ of the NADPH produced in metabolism arises via the pentose phosphate shunt, requiring the enzyme glucose-6-phosphate dehydrogenase. Knocking out this enzyme leads to increased NADH production by the tricarboxylic acid cycle and conversion of NADP → NADPH. The growth rate of the knockout strain is comparable to that of the parent.

In principle, redundancy – more obviously, substitutional redundancy – should permit compressibility in the description of a network, and thereby a reduction in its complexity relative to a nonredundant network of equal size and comparable topology.

18. Network structure and dynamics

For some networks such as metabolic pathways or patterns of traffic on city streets, the *dynamics* of the system depend on the transmission capacities of the links. In molecular biology, metabolic pathways and signal transduction cascades are networks that lend themselves to pathway and flow analysis. For control and signaling pathways, much is known about the mechanisms of individual elements, and understanding their integration is a subject of current research.

19. Structures of regulatory networks

Regulatory interactions are organized into linear signal transduction cascades, and reticulated into control networks. Any regulatory action requires (1) a stimulus, (2) transmission of a signal to a target, (3) a response, and (4) (in most cases) a "reset" mechanism to restore the resting state. Many regulatory actions are mediated by protein–protein complexes. Transient complexes are common in regulation, as dissociation provides a natural reset mechanism.

Control, or regulatory networks, are assemblies of *activities*. They:

1. *tend to be unidirectional.* A transcription activator may stimulate the expression of a metabolic enzyme, but the enzyme may not be involved directly in regulating the expression of the transcription factor.
2. *have a logical component.* It is not enough to describe the connectivity of a regulatory network. Any regulatory action may stimulate or repress activity of its target. If two interactions both influence a common target, activation may require *both* stimuli (logical "and"), or *either* stimulus may suffice (logical "or").
3. *can produce dynamic patterns.* Signals may produce combinations of effects with specified time courses. Cell-cycle regulation is an example.

20. Common motifs in biological control networks

Certain patterns of connectivity recur frequently in regulatory networks. These building blocks contribute to higher levels of organization on which a quantitative definition of network complexity will ultimately depend. Shen-Orr *et al*. (2002) have described: the *fork*, the *scatter*, and the *"one-two punch"* (a phrase from the boxing ring) (see Figure 2).

The *fork*, or the single-input motif, transmits a single incoming signal to two outputs. Generalizations include more downstream genes under common control (more tines to the fork), and autoregulation of the control node. Forks can achieve general mobilization. Moreover, if the genes regulated have different thresholds for activation, the dynamics of building up of the signal can produce a temporal pattern of successive initiation of expression of different genes.

The *scatter* configuration, also called the multiple input motif, can function as a logical "or" operation: both downstream targets become active if *either* of the input impulses is active. Note that the scatter pattern is a superposition of two forks.

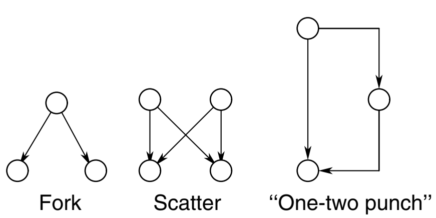

Figure 2 Three common substructures of regulatory networks: the fork, the scatter, and the "one-two punch"

The *"one-two punch"*, also called the "feed-forward loop", affects the output both directly through the vertical link and indirectly and subsequently through the intermediate link. This motif can show interesting temporal behavior if activation of the target requires simultaneous input from direct and indirect paths (logical "and"). Because the buildup of intermediates requires time, the direct signal will arrive before the indirect one. A short pulsed input will not activate the output – by the time the indirect signal builds up, the direct signal is no longer active. The system can thereby filter out transient stimuli in noisy inputs.

To identify common motifs that are similar but not identical, it is necessary to compare different networks (or subnetworks) and measure the differences. The model of such calculations for sequences is based on alignment. Berg and Lässig (2004) have presented an algorithm for alignment of subgraphs, and used it to identify higher-order motifs in networks.

21. Reconfiguration of networks – another level of dynamics

The transcription regulation network in yeast includes 142 genes that encode transcription regulators, and 3420 that encode target proteins exclusive of transcription regulators, corresponding to approximately half the known proteome of *Saccharomyces cerevisiae*. The 7074 known regulatory interactions among these genes include effects of regulators on one another and of regulators on nonregulatory targets.

The high ratio of interactions-to-transcription regulators implies that individual regulatory molecules do not have single, dedicated activities (as most metabolic enzymes do). Instead, the network involves the coordinated activities of many components.

The regulatory network achieves versatility and responsiveness through an ability to reconfigure its connectivity. Babu *et al*. (2004) compared changes in the networks controlling yeast gene expression patterns, in different physiological regimes: cell cycle, sporulation, diauxic shift (the change from anaerobic fermentative metabolism to aerobic respiration as O_2 levels increase), DNA damage, and stress response. Cell cycling and sporulation involve the unfolding of endogenous gene expression programs; the others are responses to environmental changes.

Different states are characterized by similarities and differences in gene expression patterns, and in the components of the regulatory network that are active. Think of the transcription factors as "hardware" and the connections as reprogrammable "software": The molecules do not change but the interactions do. In different states, many transcription regulators change most, or a substantial part, of their interactions. In particular, the set of transcription regulators that form the hubs of the network – those with many outgoing nodes that form foci of control – differs in different states. Some hubs are common to all states, but others step forward to take control in different physiological regimes.

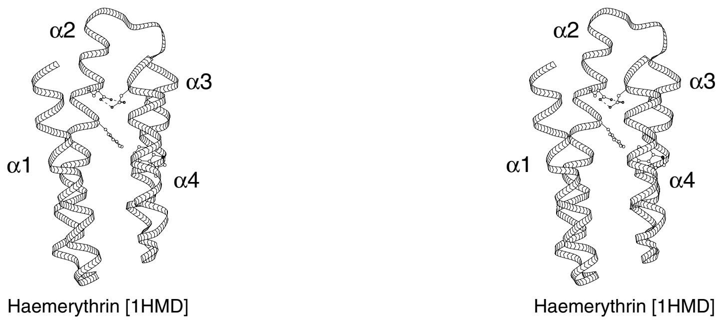
The changes in the active interaction patterns alter the topological characteristics of the network. Under panic conditions – DNA damage and stress – the average number of genes under control of individual transcriptional regulators increases, the average minimal path length between regulator and target decreases, and the

clustering becomes less dense (i.e., there is less interregulation among transcription factors). This corresponds to a need for fast and general mobilization. Normal circumstances – cell-cycle control for instance – allow for a more dignified and precise regulatory state, permitting finer control over the temporal course of expression. In cell-cycle control and sporulation, there is a much denser interregulation among transcription factors, and longer minimal path lengths between transcriptional regulators and target genes.

Different physiological states also differ in their usage of the common motifs – fork, scatter, and "one-two punch". Forks are more used in conditions of stress, diauxic shift, and DNA damage. They satisfy the need for quick action. The "one-two punch" motif is more common in cell-cycle control. This is consistent with the need for a signal from one stage to be stabilized before the cycle proceeds.

Much of evolution proceeds toward greater specialization. Many evolutionary pathways show a trade-off between specialized adaptation and generalized adaptability. Regulatory networks are an exception. Evolution has produced structures that are both specialized *and* versatile. The reconfigurability of regulatory networks allows them to respond robustly to changes in conditions, by creating many different structures, specialized to the conditions that elicit them. This also adds additional dimensions to their complexity.

22. Complexity of protein structures



Anyone who has tried to assemble a "do-it-yourself" furniture has encountered structural complexity. Many have suspected that the difficulty lies in the complexity of the description rather than the complexity of the structure (which in a way echoes the ideas of Kolmogorov).

A paradox in attempts to apply Kolmogorov's ideas to protein structures is that the shortest representation of a protein structure is an amino acid or DNA sequence. In this context, the ribosome is a decompression algorithm! (Protein structures are also representable as distance matrices, with the position, orientation, and enantiomorph undetermined (Crippen and Havel, 1988). It is interesting that proteins have one-, two-, *and* three-dimensional representations!)

23. Representation and analysis of protein-folding patterns as networks

If we put aside the representation of protein structures by their sequences, we know that protein structures show a very wide variety of topologies, some apparently more complex than others. Related proteins tend to retain, but unrelated proteins may share, similar folds. Visual examination of structures has led to qualitative classifications of protein-folding patterns (see, e.g., Lesk, 2001).

What is the essence of a protein-folding pattern? If it is defined by the order along the chain of the helices and strands of sheet, and the geometry of interaction of the pairs of secondary structure elements that are in contact, then this information

(a)

Haemerythrin [1hmd]				
	α1	α2	α3	α4
α1	α1	↑↓ **S**		↑↓ **S**
α2	↑↓ **S**	α2	↑↓ **S**	| | **D**
α3		↑↓ **S**	α3	↑↓ **S**
α4	↑↓ **S**	| | **D**	↑↓ **S**	α4

(b)

Figure 3 (a) Structure of haemerythrin, a 4-helix bundle (Protein Data Bank code 1hmd). The chevrons indicate the direction of the polypeptide chain, from N- to C-terminus. (b) Tableau representation of its folding pattern. The rows and columns are labeled by the helices appearing successively in the chain, α_1, α_2, α_3, and α_4, and these labels are repeated along the main diagonal. The off-diagonal elements encode the relative orientation of the helices that are in contact (for details, see Lesk, 1995; Lesk, 2003)

can be encapsulated in a square symmetric matrix or tableau (Lesk, 1995; Lesk, 2003). The rows and columns are labeled by the elements of secondary structure, α-helices and strands of β-sheet, in order of appearance in the amino acid sequence. Each off-diagonal position is either blank if the corresponding pair of secondary structure elements is not in contact or encodes the relative orientation of secondary structure elements that are in contact. It is convenient to list the names of the secondary structure elements along the main diagonal (see Figure 3).

24. Use of the tableau representation to measure complexity of protein-folding patterns

Can the ideas of Kolmogorov be applied to the tableau or other representations of protein-folding patterns, to measure complexities of protein structures? What is the minimal amount of information that specifies a folding pattern?

The tableau representation of protein-folding patterns makes it possible to address these questions. By regarding the tableau as a succession of diagonals, we can ask for the smallest part of the tableau that uniquely determines the protein fold. The main diagonal contains only the *order* of secondary structural elements. This

information alone does not specify the folding pattern; for all α-helical proteins contain the same main diagonal: $\alpha 1$, $\alpha 2$, $\alpha 3$, ... One can then ask whether the main diagonal plus the adjacent diagonal of such a tableau – which together specify the secondary *and* supersecondary structure – are enough to uniquely determine the fold; if not, how many diagonals are necessary? Alternatively, Przytycka *et al*. (1999) have shown that the sequence of secondary structural elements, together with the lengths of the loops between them, generally suffice to determine the protein fold. These approaches, the subjects of current research, involve an application of Kolmogorov's ideas to the analysis of complexity of structures.

25. Complexity of the protein folding process

Another measure of protein structural complexity is *contact order* (Plaxco *et al*., 1998). Contact order measures the average separation in the *sequence* of residues that are close by in *space:*

$$\text{Contact order} = \frac{1}{LN}\sum(i-j) \tag{4}$$

where L is the number of residues in the protein, N is the number of residues in contact, $i-j$ is the distance in the sequence between residues i and j, and the sum is taken over all pairs of residues in contact.

Not only does this sound like a reasonable measure of structural complexity according to naive notions, it may well correspond to the proteins' idea of complexity: for proteins with simple two-state folding behavior, the folding rate is strongly correlated with the contact order.

In more complex cases with multiple transition states or even stable intermediates, the folding process of a peptide or protein is describable in terms of a network. The nodes of the network are the localized free energy minima in conformation space, and the edges describe the dynamics of interconversion among the nodes.

Krivov and Karplus (2004) analyzed the potential energy surface for folding of the β-hairpin from protein G, a 16-residue peptide with a well-defined native structure. They generated a population of 2×10^5 conformations by molecular dynamics at 360 K for 4 µs. By clustering the conformations, Krivov and Karplus showed that the conformational space for folding contains many basins. The topology of fold space can be regarded as broken up into discrete states, each a distinguishable cluster of related conformations. Continuous trajectories between the discrete states of this model must exist, but if the system spends most of its time in states corresponding to these clusters, it is appropriate to regard folding space as a network and the folding process as a succession of transitions within this network (see Figures 4 and 5).

26. Conclusions

The subject of complexity will be a fertile source of research problems in biology for many years. The basic challenge is to define concepts that will support

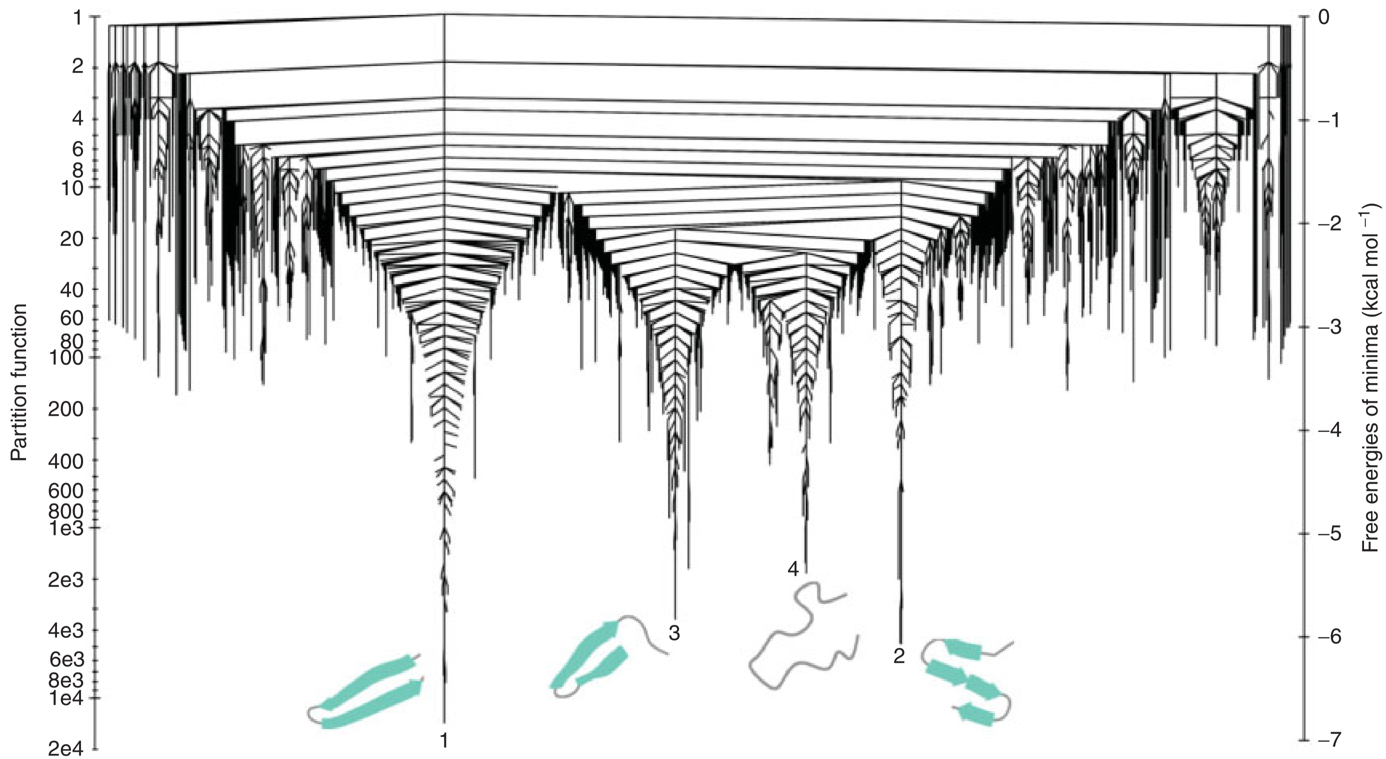


Figure 4 Plot of conformation space for the β-hairpin from protein G. The minimum-energy conformation, 1, corresponds to the native state. Other states appear with different energy distributions and with different barriers between them. The conformations illustrated (green) are representative of the states in the cluster and not necessarily those uniquely at the minimum-energy point of the cluster. Because the topology of conformation space is reduced in this figure to one-dimension (the horizontal axis), the distribution of probabilities of interconversion between states is not evident from this diagram (see Figure 5) (Reproduced from Krivov and Karplus (2004) by permission of National Academy of Sciences U.S.A.)

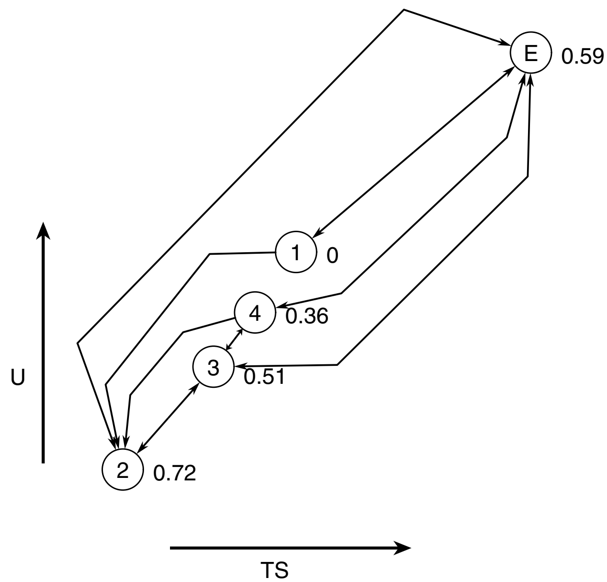

Figure 5 Transition matrix between major nodes in the folding network for the β-hairpin from protein G. (Redrawn from data in Krivov, S. V. and Karplus, *loc. cit.*) The labeled circles are plotted on axes showing the values of average energy U and TS of each state depicted in Figure 4. The numbers next to the circles are the relative Helmholtz free energies of the states, relative to the lowest (state 1). Lines of constant Helmholtz free energy are diagonal lines in the southwest–northeast direction. The fact that such a line almost passes through all the points shows that the differences in free energy are small compared to the individual differences in U and TS. The end states of the folding process are E (denatured) and 1 (hairpin, highest stability – see Figure 4). In understanding the relationship between this and the previous figure, recognize that the values of U and TS are computed as an average over the states in the basin surrounding the structure depicted, and that the transition probabilities are determined by features of the states near the *top* of the barriers, not by the conformations at the minima. The transition probabilities between the states, which determine the folding pathway, are very unevenly distributed. (Note, from the absence of arrows, the very low probability of a state 2 → state 4 and a state 1 → state 2 transition.) In particular, transitions between the E state and states 3 and 4 are much more probable than any others. Nevertheless, the major folding transition is directly from E → 1, and the other states, including states 3 and 4, are "off-pathway". In the language of networks, the E state is the "hub" of the folding process.

analysis of data on sequences, expression patterns, structures and interactions of proteins and nucleic acids, and metabolic and regulatory networks. In this article, I have tried to provide as background, for the general biological researcher, results of analyses of complexity in other fields, in a way applicable to biological research.

The basic ideas for the reader to take away are:

- Complexity is related to the extent to which knowledge of part of an object allows prediction of the whole, or the extent to which the portion of a process already observed determines the part that is yet to come.

- This characterization of complexity is based on the ideas of Kolmogorov that the complexity of a sequence depends on its shortest possible description, and the related idea that the complexity is related to compressibility.
- Computational complexity, in principle, describes characteristics of problems, but is related to the complexity of processes.
- Complexity is a characteristic both of the structure of an object and of its dynamics.
- Many biological phenomena, including metabolic and regulatory networks, and even protein structures and folding pathways, are amenable to treatment by the same basic ideas that have been well worked out for sequences. However, our understanding of the underlying principles of their structures and dynamics is only now emerging.

Specialist Review

Modeling by homology

Kenji Mizuguchi
University of Cambridge, Cambridge, UK

1. Introduction

Comparison of the three-dimensional (3D) structures of homologous proteins shows a clear correlation between structural similarity and sequence identity (Figure 1). (Note that homology means common ancestry (Reeck *et al*., 1987).) Chothia and Lesk's analysis (Chothia and Lesk, 1986) was among the first to quantify this relationship; they defined the common core of a homologous protein family to be the superimposable elements of secondary structure (*see* Article 76, **Secondary structure prediction**, Volume 7) and adjacent residues, and obtained a relationship between the root mean square deviation (RMSD) of the core backbone atoms and the percentage sequence identity (PID). Although for distantly related protein pairs (with PID $<$ 25%), the common core may account to as little as 40% of the structure, the equivalent atoms can be still superimposed with a reasonably low RMSD ($<\sim$1.5 Å).

Therefore, if a homologous relationship can be established between a pair of proteins and the 3D structure of one of them has been determined experimentally, it is possible to predict the structure of the other on the basis of the known structure. The prediction accuracy increases as the PID between the two proteins increases. This possibility had been realized long before the formal relationship between sequence and structural similarity, as discussed above, was established. Browne *et al*. (1969) proposed a model of α-lacalbumin based on the crystal structure of lysozyme. Subsequently, this "modeling by homology" approach was more formally established, and fully automated methods for comparative (or homology) modeling have been developed (for example, by Sutcliffe *et al*., 1987a,b; Sali and Blundell, 1993).

In the 1969 paper, Browne *et al*. mentioned, " ... the very many protein molecules may belong to a comparatively small number of families. It may be possible to derive the structures of all the members of a family relatively easily once one or two have been analysed in detail. Certainly this approach seems more promising at the moment than does the prediction of unique protein structures from chemical information alone." Thirty-five years on, comparative modeling remains the most reliable method for predicting protein 3D structures in atomic detail, and there are

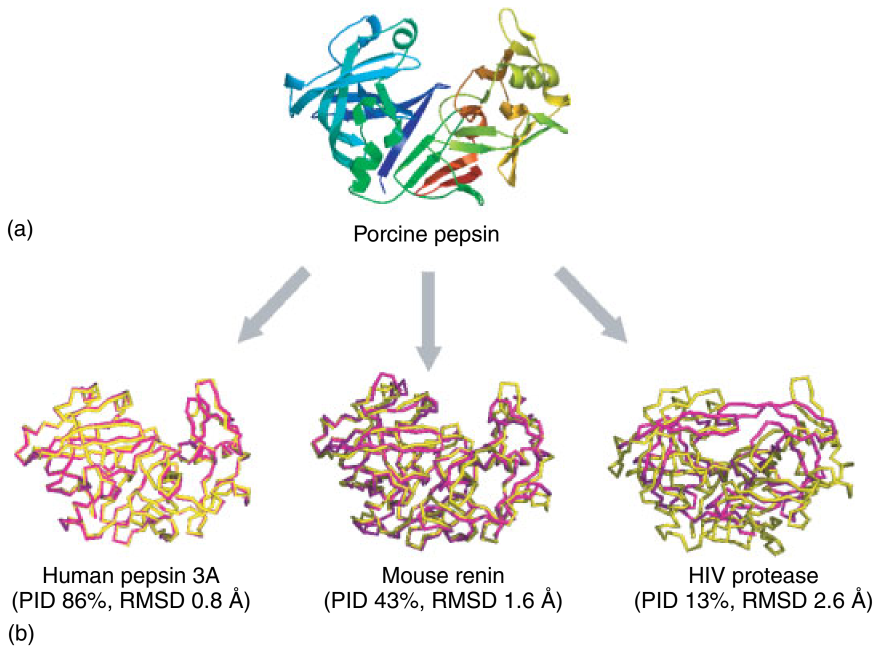

Figure 1 Relationship between sequence and structural similarity among homologous proteins. PID: percentage sequence identity; RMSD: root mean square deviation of the equivalent Cα atoms (see text). Figure generated with PyMOL (**http://www.pymol.org**)

now databases (Kopp and Schwede, 2004; Pieper *et al*., 2004) that provide easy access to a large number of automatically built comparative models.

Key to the success of this approach is to identify homologous protein pairs. Conventionally, this was achieved by standard sequence comparison methods. To apply comparative modeling, BLAST (Altschul *et al*., 1990) or other sequence database searches must identify one or more homologs of known structure (often referred to as "templates" or "parents" in comparative modeling although they are more like cousins in evolution). If no obvious homologs can be obtained in this way, searching for potential templates (remote homologs or even analogous structures with no evolutionary link) is considered a different kind of challenge. A series of new methods (Bowie *et al*., 1991; Jones *et al*., 1992), now collectively known as *fold recognition techniques*, have been developed for this purpose. Comparative modeling and fold recognition have been considered related but separate attempts, as demonstrated in two distinct categories of the Critical Assessment of Techniques for Protein Structure Prediction (CASP (*see* Article 73, **CASP**, Volume 7; Moult *et al*., 2003)) exercises.

In recent years, however, significant advances have been made to identify distant evolutionary relationships between proteins that show very weak sequence similarity. As a result, the conventional distinction between comparative modeling

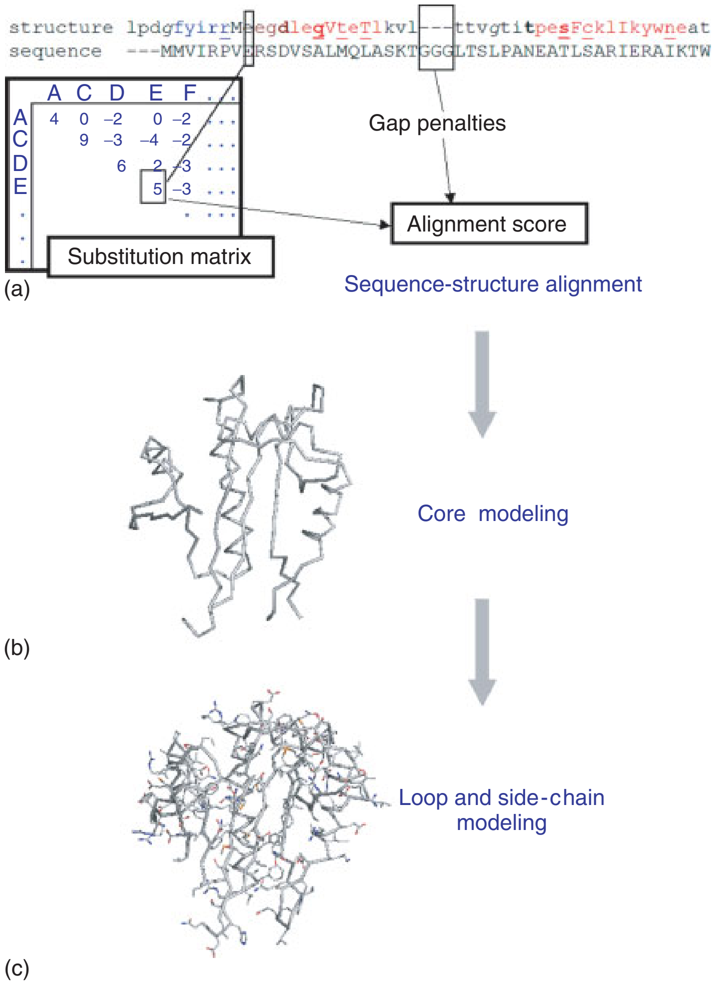

Figure 2 From sequence-structure alignment to full atomic model. (a) Alignment of the sequences of the target protein (in black) and the template (of known 3D structure, where secondary structure elements are shown in color; red, α-helices; blue, β-strands, maroon, 3_{10} helices; coil, black). (b) Cα trace of the core model. (c) Full atomic model with loop and side-chain atoms

and fold recognition has become obscured and the concept of comparative modeling can be now extended to cover any model building attempt based on homology (Kinch *et al*., 2003; Mizuguchi, 2004). Therefore, the following discussion will treat comparative modeling and fold recognition within a common framework, with particular emphasis on the latter.

Traditionally, comparative modeling consists of several distinct steps (Figure 2) (Blundell *et al*., 1987; Tramontano, 1998; Marti-Renom *et al*., 2000):

1. Template (parent) identification and sequence-structure alignment
2. Core building

3. Loop building
4. Side-chain building.

Although some methods, including the popular program MODELLER (Sali and Blundell, 1993; Fiser *et al.*, 2000), rely on finding solutions that optimally satisfy distance restraints and do not take the exact steps above, they can be still characterized by this generic scheme. In the following sections, I will first describe fold recognition techniques as a key component of the initial stage of comparative modeling. Since serious challenges remain in the model-building stages (steps 2–4 above) of conventional comparative modeling methods (Tramontano and Morea, 2003), these will be discussed in the subsequent section. Finally, a brief comment will be made on the accuracy of models.

2. Template identification

In recent years, there has been a change in the way the question of identifying homologs of known structure has been addressed. Conventional sequence database searching methods ask the question, "Is the query sequence A homologous to sequence B?", whereas more modern methods ask, "Does sequence A belong to family B?". The former (such as FASTA (Pearson and Lipman, 1988) and BLAST (Altschul *et al.*, 1990)) perform pairwise searches, where the query sequence is compared with each sequence in the database and their similarity quantified. Normally, an amino acid substitution matrix is used to quantify the similarity between the two sequences (Figure 2, top *see* Article 67, **Score functions for structure prediction**, Volume 7). This is necessary because simply counting the number of complete matches (i.e., using PIDs) is known to be inadequate to judge the likelihood of common ancestry for distantly related proteins (Brenner *et al.*, 1998). The use of a 20-by-20 score matrix is based on the observation that during the course of evolution, substitutions between certain amino acid pairs were more frequent than others because they preserved the chemical and structural environments (and thus, these mutations are more likely to be accepted by natural selection) (Dayhoff *et al.*, 1978). In addition, insertions and deletions are dealt with by using a set of parameters called *gap penalties* (Figure 2, top).

Newer methods go further than this and use the information about a group of sequences that are already known to be homologous. In addition to the general tendency to preserve the chemical nature of the amino acid side chain, the degree of amino acid conservation within a family of homologous proteins depends on the structure and function of these proteins. For example, the surface positions are more likely to be variable than the buried positions and catalytic residues are highly conserved. These differences give rise to highly conserved and less conserved regions in a multiple sequence alignment of the family members. Thus, it is possible to derive a family-specific "profile" of patterns of amino acid substitutions and use it to evaluate the likelihood of membership for new sequences.

There are several methods for constructing these profiles. A sequence profile (Gribskov *et al*., 1987) is a natural extension of amino acid substitution matrices; it provides a set of substitution scores for each position in the multiple sequence alignment, from which the profile is made. It adopts the form of a matrix in which the number of rows is equal to the length of the original alignment and the number of columns is 20 to store the substitution scores to each of the 20 possible amino acids. Since a profile contains position-specific information about the sequence conservation within a homologous family, it is also called a *position-specific scoring matrix* (PSSM).

The patterns of amino acid substitutions can be also expressed using mathematical representations known as hidden Markov models (HMMs) *see* Article 98, **Hidden Markov models and neural networks**, Volume 8 (Durbin *et al*., 1998). From a machine-learning point of view, both profiles and profile HMMs are considered a generative probability model; the parameters of a statistical model representing a homologous family are derived from the sequences of known members of the family (positive training examples) and the model assigns a probability to any new sequence to assess the likelihood of its membership to the family of interest. There are also discriminative approaches (Jaakkola *et al*., 2000), in which the parameters are estimated using both positive training examples and negative training examples (proteins that are known to be nonmembers of the family being analyzed) and machine-learning techniques such as support vector machines (*see* Article 110, **Support vector machine software**, Volume 8) are applied (Liao and Noble, 2003).

The ability of these methods to identify distant homologs can be tested by using a set of proteins, the structures of which are already known. These tests have shown (for example, by Lindahl and Elofsson, 2000) that the family-based methods (using information derived from multiple sequence alignments) perform significantly better than conventional pairwise comparison methods.

Some of these methods offer a user-friendly Web interface and have been widely used in genome annotation. For example, the HMM-based method HMMER (Eddy, 1998) is the default search engine for the Pfam (Bateman *et al*., 2002) and Smart (Schultz *et al*., 1998) databases. PSI-BLAST (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7) (Altschul *et al*., 1997) is another popular tool for detecting remote homologs.

Most of the methods discussed so far perform general sequence–sequence comparison and are not restricted to searches for proteins of known 3D structure. Recent benchmark results show that these methods still miss a significant fraction of homologs, which adopt similar structures to that of the query (Fischer *et al*., 2003). Can we improve homolog detection further, particularly in our specific situation where we need to identify proteins of known structure? The answer seems yes and there appear to be two possible directions; (1) "fold recognition methods" to utilize specific information about protein 3D structure and (2) profile–profile methods to extend the family-based recognition approach. In discussing these methods, we need to diverge from pure sequence–sequence comparison and deal with specific issues regarding sequence-structure comparison. Therefore, it is more appropriate to discuss details of these methods in the next section.

3. Sequence-structure alignment

Once one or more homologs of known structure have been identified, it is necessary to align the query sequence against that of a template. Although the template identification (discussed in the previous section) and the alignment generation are intimately related and they are normally performed simultaneously, there are some issues unique to alignment. Theoretically, the optimal choices for some parameters (such as gap penalties) may be different for database searching and for alignment (Vingron and Waterman, 1994). In the first case, the objective is the best contrast between sequences related to the query and all others, whereas in the latter case, the alignment should cover the query sequence as much as possible.

For comparative modeling, this issue is particularly important. Standard sequence–sequence comparison methods normally adopt a local alignment algorithm. These methods are good at capturing the most conserved regions shared between related proteins but these regions may not cover the entire structural domains and are indeed often smaller than the known structures.

More generally, if our aim is to generate sequence-structure alignments, it is possible to extract specific information about conserved features from known structural families and incorporate that into our search and alignment strategies. This approach is adopted by fold recognition methods (the first direction mentioned at the end of the previous section).

As the number of experimentally defined protein structures continues to grow, protein family and classification databases have played important roles in organizing essential structural information. These databases can be manually curated (such as SCOP (Murzin *et al*., 1995)) or constructed using semiautomated (such as CATH (Orengo *et al*., 1997) and HOMSTRAD (Mizuguchi *et al*., 1998b)) and fully automated methods (FSSP (Holm and Sander, 1994)). Family-specific conserved features in sequence and structure can be obtained from these databases and such information is used, directly or indirectly, in many fold recognition methods.

Structural information can be used in several different ways in homolog detection and alignment (Mizuguchi, 2004). There are “threading-type” approaches, in which the query sequence (a “string”) is threaded through the backbone coordinates of a known protein structure and the degree of compatibility between the sequence and the structure is evaluated using knowledge-based potentials (Sippl, 1995). The programs GenThreader (Jones, 1999), PROSPECT (Xu and Xu, 2000), RAPTOR (Xu *et al*., 2003) are a few examples (*see* Article 72, **Threading for protein-fold recognition**, Volume 7). Structural information has also been incorporated directly into an alignment algorithm, which produced some promising results (Zhang *et al*., 2003).

There are “structure-aided sequence comparison” methods, whose operations are analogous to that of family (profile)-based sequence–sequence comparison methods, but with information about the 3D structures of proteins incorporated. The program 3D-PSSM (Kelley *et al*., 2000) uses PSSMs that are derived from multiple sequence alignments as in PSI-BLAST and other profile-based methods. The multiple sequence alignments, however, are based on the 3D structures of the family members and thus, are more reliable (as structure is better conserved than sequence during the course of evolution). The method also uses predicted secondary

structures and some form of knowledge-based potential. In the program FUGUE (Shi *et al*., 2001), the similarity between the query sequence and a potential homolog is quantified using environment-specific substitution tables (ESSTs) (Overington *et al*., 1990; Luthy *et al*., 1991). As mentioned in the previous section, amino acid substitutions are structurally conservative and the local environment of each amino acid affects the likelihood that it will change into other amino acids during the course of evolution. Thus, it is possible to derive amino acid substitution scores depending on the local environment and compile them in ESSTs. If we know the structure of one of the proteins being compared (as in the case of sequence-structure alignment), we can use ESSTs, instead of a generic amino acid substitution matrix, to evaluate an alignment score between the sequence and the structure.

Another feature of the program FUGUE is that a profile is constructed for both a database structure (using the ESSTs, combined with a multiple sequence alignment of homologs) and a query sequence (from its homologous sequences). Thus, the program performs "profile–profile comparison", an example of the second extension (see the previous section), from "sequence-profile" comparison to "profile–profile" comparison. If the change from pairwise methods (comparing a sequence with a sequence) to family-based profile methods (comparing a sequence with a profile) has proven a significant improvement, it is natural to extend this and develop methods for comparing a profile with a profile. There are different ways of defining similarity between profiles (Rychlewski *et al*., 2000; Yona and Levitt, 2002) but when properly parameterized, these methods appear to outperform conventional sequence-profile methods. Combining predicted secondary structures help but profiles can still be constructed without referencing to any known 3D structures. Some profile–profile methods even achieve performances comparable to those of the best fold recognition methods despite using no explicit structure information (Ginalski *et al*., 2003b).

Recent benchmark results show that (Fischer *et al*., 2003) many of these newer methods perform better than PSI-BLAST, a standard high-performance sequence–sequence comparison program. This is in terms of both the sensitivity and specificity of homolog identification (how many homologs can a method detect without producing many false-positives?) and the quality of sequence-structure alignments. The latter can be evaluated by comparing the sequence-structure alignment with the structure–structure alignment (*see* Article 75, **Protein structure comparison**, Volume 7).

Many of these methods are available as fully automated Web servers. There are also special servers called meta servers (Bujnicki *et al*., 2001; Douguet and Labesse, 2001). They collect predictions from individual servers and produce consensus predictions, which are generally more reliable than the results from the individual servers. For example, 3D-jury (Ginalski *et al*., 2003a), Pcons (Lundstrom *et al*., 2001), and shotgun (Fischer, 2003) are popular and successful meta servers.

4. Model building

A conventional approach to obtaining the atomic coordinates of the target protein consists of three steps: (1) constructing a model for the core of the query

protein, (2) building the structurally variable regions, and (3) modeling side-chain conformations.

Despite many efforts, the currently available techniques cannot correct errors introduced in the earlier stage; if the choice of the template(s) is not optimal and/or the alignment between the target protein and the template(s) contains errors, the quality of the final model can never exceed that of a model based on a better alignment. This is because the current technology is essentially the "copy-from-the-template" approach; in many cases, even the best model is no closer to the experimental structure than the closest homologous structure (Tramontano and Morea, 2003).

There are a few new approaches that show the potential to produce models better than the closest homolog (Kolinski *et al*., 2001; Contreras-Moreira *et al*., 2003; Fischer, 2003) and in many applications, it is desirable to produce complete atomic models rather than alignments alone. Therefore, specific issues regarding each of the model building steps will be briefly described below. More detailed descriptions of the techniques used can be found in recent reviews such as (Marti-Renom *et al*., 2000).

4.1. Core building

In its simplest form, core building can be described as follows: given an alignment between the sequence of the protein of interest and that of a template, the coordinates of the template atoms where the conformations are conserved between the template and the target are copied. One obvious choice of the conserved core (also called structurally conserved regions – SCRs) is the backbone atoms of all the nongapped regions in the alignment. By definition, copying the conserved core will provide an accurate prediction of (part of) the structure of the protein of interest and if the PID between the template and the target is high, the nongapped regions will be indeed a good approximation of the conserved core.

As the PID decreases, however, more structural changes will be observed. One of the most important challenges here is to predict the changes in the packing of secondary structure elements between homologous structures. Amino acid replacements of hydrophobic core residues are usually accommodated by small shifts of secondary structure elements (Lesk and Chothia, 1980). Therefore, simply copying the template coordinates for the nongapped regions may not model these changes accurately. This problem is related to a more general issue of how to define the conserved core when multiple template structures are available. The difficulty of quantifying shifts in secondary structures in homologous proteins was clearly documented in the pioneering review of Blundell *et al*. (1987) and it remains a challenge.

4.2. Loop modeling

A core model lacks the atomic coordinates of regions corresponding to insertions and deletions, which occur mostly in exposed loops that connect secondary

structure elements. By definition, the most significant variations in protein structures are observed in these structurally variable regions (SVRs) and predicting their structures is among the most difficult parts of model building. (Note that SVRs and loops are not always the same; active sites in enzymes usually consist of loops but they are conserved among the members of the family. In this article, the commonly adopted term "loop modeling" is used for convenience.)

Several approaches have been adopted. Knowledge-based methods search a database of known structures for a backbone fragment that fits the anchoring region of a loop. This approach is particularly effective when a set of empirical rules are derived from database structures to understand and predict the sequence-structure relationships for certain types of loops (Sibanda and Thornton, 1985; Chothia *et al*., 1989). Ab initio approaches, on the other hand, rely on conformational sampling and selection using potential energy functions or other scoring methods. Numerous methods for searching and scoring have been proposed (see, for example, Fiser *et al*., 2000 and references therein). The latest methods (de Bakker *et al*., 2003; DePristo *et al*., 2003; Jacobson *et al*., 2004) can build loops up to eight residues with reasonable accuracy (<2.3 Å backbone RMSD) when the experimental core structures are supplied. It is still a challenge to build loops (even of moderate lengths) when the remainder of the structure contains errors.

4.3. Side-chain modeling

After a model for the backbone, side-chain conformations have to be predicted to complete the full atomic model. Apart from the "copy-from-the-template" approach, which can be applied throughout all model building steps, side-chain placements normally consist of two elements: a rotamer library and combinatorial optimization.

It has been observed that each side chain adopts a limited number of preferred conformations referred to as *rotamers*. A rotamer library is a collection of rotamers for each residue type, usually derived from statistical analysis of known structures (Ponder and Richards, 1987; Dunbrack and Karplus, 1993; Lovell *et al*., 2000).

Although rotamer libraries can reduce the possible number of side-chain conformations significantly, the optimal conformation of a particular side chain depends on its interactions with other side chains (a combinatorial problem). To obtain the best combination of all side-chain conformations, an efficient search algorithm is required. A dead-end elimination algorithm (Desmet *et al*., 1992) is adopted in the commonly used program SCWRL (Bower *et al*., 1997). Other approaches include a mean-field algorithm (Mendes *et al*., 2001) and Monte Carlo methods.

5. Accuracy of models

As described in the previous section, the accuracy of comparative models is primarily determined by the sequence similarity between the target and the template proteins. Quantitative relationships between PID and structural similarity, such as

the one derived by Chothia and Lesk (1986), can provide general ideas. As a rule of thumb, below are several cutoffs estimated from different types of analysis:

30% – Comparison of models and experimentally determined structures for the CASP targets has shown that models based on templates with >30–35% PID generally have reasonably low alignment and structural errors (Vitkup *et al*., 2001). This 30% cutoff is often quoted as the minimum PID to cover fold space in structural genomics projects.

40% – For pairs of sequences with >40% PID, sequence–sequence comparison methods can produce alignments that are almost identical to those based on the direct comparison of 3D structures (for example, Shi *et al*., 2001). This suggests that there are minimal alignment errors when templates with >40% PID exists and that the model accuracy will be accordingly high.

Systematic analyses of the functional diversity of protein families have also identified a 40% PID threshold, above which precise function, as defined by the first three digits of the Enzyme Commission number, is conserved (Todd *et al*., 2001). Therefore, models based on templates above this threshold can be used to discuss detailed features of protein function.

How about models based on distant homologs? Even though the overall accuracy of these models may be limited, building models can be still useful in several different ways.

First, building models and examining conserved structural features by itself can provide additional support for the homology detection and alignment. Tools such as Verify3D (Luthy *et al*., 1992) and ProsaII (Sippl, 1993) can be used for this purpose. These tools evaluate the compatibility between a sequence and a predicted 3D structure using measures (normally knowledge-based potentials), which are often not used by homolog detection and alignment methods. Therefore, high model scores by these evaluation tools provide an independent line of evidence for the distant relationship identified. These evaluation tools, combined with manual examination of models and alignments (Mizuguchi *et al*., 1998a), can also help identify better templates or correct alignment errors and this iterative approach is an efficient way to improve model building on the basis of remote homologs (Burke *et al*., 1999; Kosinski *et al*., 2003). Note that good stereochemistry, as assessed by programs such as PROCHECK (Laskowski *et al*., 1993) and WHATCHECK (Hooft *et al*., 1996), does not guarantee closeness to the experimental structure.

Second, while functional diversity can be commonly observed for distantly related proteins, they tend to retain common features and furthermore, certain specific features, such as the reaction chemistry of enzymes, can be highly conserved. Thus, it is possible, for example, to discuss detailed mechanism of action on the basis of a model for the region near the catalytic site, even though the model is based on a distantly related homolog (e.g., Shirai *et al*., 2001; Shirai and Mizuguchi, 2003). These analyses typically present hypotheses that can be tested by site-directed mutagenesis and other experiments.

6. Conclusions

Modeling by homology remains the most reliable method for predicting protein 3D structures. With recent advances in methods for detecting distant homologs

and the increasing number of experimentally determined structures, this approach has opened up a wider range of applications. The technique involves several distinct stages, of which the first part, the homolog identification and sequence-structure alignment, is crucial for the success of the following steps. Fundamental problems remain but advances in the techniques at each stage may eventually provide reasonably accurate models for essentially any protein.

Acknowledgments

I thank Simon Lovell for reading the manuscript critically, Mark DePristo and Rick Smith for comments on loop and side-chain modeling and for support from the Wellcome Trust.

Haruki Nakamura
Osaka University, Osaka, Japan

Kim Henrick
MSD-European Bioinformatics Institute, Hinxton, UK

1. Introduction

The Protein Data Bank (PDB) (Berman *et al*., 2000; Bernstein *et al*., 1977) is the repository for macromolecular structures determined by experimental methods, including X-ray crystallography, NMR spectroscopy, and cryo-electron microscopy. The PDB, founded in 1971 with seven structures, is one of the oldest biological databases and in January 2004 contained over 23 500 entries. The archive's growth has been accompanied by increases in both data content and the structural complexity of individual entries. The PDB data archive is an important tool for all biological researchers and is free to all as a collection of FTP-accessible files. In November 2003, the Worldwide Protein Data Bank (wwPDB) (Berman *et al*., 2003) was established to ensure the continuation of the PDB as a single, uniform, and enduring archive, with an agreement between the Research Collaboratory for Structural Bioinformatics (RCSB, **http://www.rcsb.org/**) (The Research Collaboratory for Structural Bioinformatics (RCSB) consortium members who are responsible for PDB management are Rutgers, the State University of New Jersey; the San Diego Supercomputer Center at the University of California, San Diego; and the Center for Advanced Research in Biotechnology/UMBI/NIST.), European Bioinformatics Institute (MSD, **http://www.ebi.ac.uk/msd**) (Boutselakis *et al*., 2003), and the Protein Data Bank Japan (PDBj, **http://www.pdbj.org/**) (Kinoshita and Nakamura, 2004).

2. PDB information content

In addition to the 3D coordinates, entries contain general information required for all depositions and information specific to the method of structure determination. The format of the PDB entries has evolved over the years. In the early days, the data were loosely structured with free text information describing how the experiment was done and what the results might mean. The current PDB entries are now well structured and computer readable. They contain the sequence and source of the macromolecules, chemistries of small molecule ligands, secondary structural descriptions, and classifications (*see* Article 69, **Complexity in biological structures and systems**, Volume 7) and qualitative descriptions of the structures (*see* Article 76, **Secondary structure prediction**, Volume 7). They also contain experimental information including crystallization conditions, crystal data, data collection and refinement statistics, and literature references. Approximately 50% of the entries contain primary experimental data, including structure factor tables (h,k,l; Fobs; sigma-Fobs) and NMR-specific data.

3. Data uniformity

A significant objective of the PDB is to make the archive as consistent and error-free as possible. Query across the complete PDB has been limited by missing, erroneous, and inconsistently reported experimental data, nomenclature, and functional annotation. The evolution of experimental methods, functional knowledge of proteins, and methods used to process these data over the years has introduced various inconsistencies into the PDB archive and has inspired different versions of the PDB format. In addition to concentrating on making current depositions to the PDB consistent, efforts are being made as part of the RCSB's Data Uniformity Project to enhance the consistency of existing entries (Bhat *et al*., 2001). The goal of these efforts is to provide a higher level of query capability through the higher curation of the database. The legacy data are checked for accuracy, uniformity, and completeness in both individual and global respects. Much progress has been achieved in this "cleanup" process by means of two complementary methods used to update and unify the archive. *File-by-file* uniformity processing brings each entry up to the current PDB format by adding records that were not present in some early entries, correcting unresolved problems, providing standard nomenclature, and evaluating data using current validation software. Additionally, key records within each PDB entry have been targeted for *archive-wide* uniformity processing, wherein data are examined and updated on certain global parameters such as synonyms, common names, and names used by other data centers to enrich the reliability of query results. The MSD group has applied a different strategy by making use of relational database technologies in a comprehensive cleaning procedure to ensure data uniformity across the whole archive. Here, each record type is matched automatically from text manipulation tools. PDBj has used an XML Schema to detect problems in the PDB archive, and efforts are in progress to combine all three sets of corrections into a new set of uniform PDB entries.

4. Deposition to the PDB

One of the reasons the PDB archive offers such a complete record of experimental structural biology is that funding agencies and scientific journals require the deposition of relevant data as a condition of financial support or publication. Two deposition tools are available. ADIT is used for data submitted to RCSB and PDBj. This tool is an mmCIF (macromolecular Crystallographic Information file) editor and contains translators between the PDB and mmCIF formats. AutoDEP is used by the MSD group.

5. Annotation and validation of the PDB

The task of formatting, annotating (*see* Article 29, ***In silico* approaches to functional analysis of proteins**, Volume 7), validating, and releasing PDB entries in a manner that maintains uniformity across the archive has been made possible by adopting well-defined software-accessible data dictionaries and controlled vocabularies (*see* Article 81, **Unified Medical Language System and associated vocabularies**, Volume 8) using mmCIF (Bourne *et al*., 1997).

The validation processes include a range of issues including authentication of source (*see* Article 36, **Large-scale, classification-driven, rule-based functional annotation of proteins**, Volume 7), authentication of versions, validation of correct methodology, conformity to standards, error checks for consistency, and outlier detection. Specific sequence checks are made to ensure that the records are consistent and are correlated with the sequence database records. The chemistry of the ligands is also carefully checked. Nomenclatures are reviewed and corrected. Geometric checks of the small and large molecules are made with special attention to stereochemistry, close contacts, and valence geometry. The database includes goodness of fit, and quality indicators for entries, chains, and residues, allowing the coordinate information to be studied in conjunction with reference data. For those crystallographic entries in which structure factors have been deposited, the map correlation indicators are included at the residue level. Accurate, consistent data along with clear indicators of quality are key aspects that make the PDB useful to a diverse community of researchers.

6. PDB FTP access

The ftp site is maintained at **ftp://ftp.rcsb.org/pub/pdb/**. It is updated weekly and contains all the coordinate and experimental data for NMR and X-ray determinations. In addition, all obsolete structures that have been replaced by updated versions are maintained. As part of the wwPDB agreement, RCSB has sole write access to this site, thus ensuring that there is a single uniform archive of PDB entries. The ftp archive is available from all three wwPDB partner sites.

7. WWW search and retrieval systems

The challenge of presenting the available information in an intuitive way to users from various backgrounds and expertise demands that the data are archived in a meaningful and flexible way that represents the hierarchy and constraints within the data. Technologies of relational database and XML-DB offer both the flexibility and the framework to achieve this goal. The wwPDB partners have applied different database technologies for the extremely complex processes of importing legacy data from the PDB, creating deposition systems with automated annotation procedures, developing molecular graphics viewers, achieving data uniformity, and integrating relevant information from other biological databases. The services are continually undergoing improvements, and users should consult the different sites for the latest search systems.

The RCSB PDB Website is available from the three member sites (Rutgers, UCSD/SDSC, and CARB/NIST) and is mirrored at the Cambridge Crystallographic Data Centre (CCDC, UK), the National University of Singapore (Singapore), Osaka University (Japan), the Universidade Federal de Minas Gerais (Brazil), and the Max Delbrück Center for Molecular Medicine (Germany).

8. Inter-database consistency

To maintain consistency between the structure and sequence databases, it is important to determine the correct sequence database cross-reference. The PDB partners maintain up-to-date cross linkages between the PDB and SwissProt (*see* Article 97, **Ensembl and UniProt (Swiss-Prot)**, Volume 8) (Bairoch and Apweiler, 2000), InterPro (Apweiler *et al*., 2001), SCOP (Murzin *et al*., 1995), CATH (*see* Article 75, **Protein structure comparison**, Volume 7) (Orengo *et al*., 1997), and PFAM (*see* Article 35, **Measuring evolutionary constraints as protein properties reflecting underlying mechanisms**, Volume 7) (Bateman *et al*., 2002). For new depositions, steps are taken to ensure that the SEQRES record in the PDB entry represents the correct amino acid sequence of the sample. Since many of the legacy PDB entries contain only the coordinates of the observed atom positions, it is difficult to obtain the complete sequence of the protein(s) studied.

9. Conclusion

The PDB is a strategic resource in modern biology. After recent successes in genome-sequencing projects, initiatives in structural genomics aim to fully understand the biological role of proteins by determining representative structures for protein families on a genomic scale. The PDB now faces the challenge of managing a massive amount of data being produced (Westbrook *et al*., 2003; Berman *et al*., 2000). Harnessing the data within the PDB and combining it with data from other resources will enable biology to continue to advance at breathtaking speed.

Acknowledgments

The RCSB PDB is supported by funds from the National Science Foundation, the office of science Department of Energy, and the National Institutes of Health. E-MSD gratefully acknowledges the support of the Wellcome Trust (GR062025 MA), the EU (TEMBLOR, NMRQUAL, and IIMS), CCP4, the BBSRC, the MRC, and EMBL. PDBj is supported by grant-in-aid from the Institute for Bioinformatics Research and Development, Japan Science and Technology Agency (BIRD-JST), and the Ministry of Education, Culture, Sports, Science and Technology (MEXT).

Short Specialist Review

Threading for protein-fold recognition

Kuang Lin
National Institute for Medical Research, London, UK

It has been observed that proteins with similar sequences, often closely related homologous, tend to have similar three-dimensional structures and functions. If their sequences and structures can be accurately aligned, corresponding amino acid residues in the alignments will be found in similar positions of the structures with similar conformations. Thus, given a protein sequence with unknown structure (often called *the query or target sequence*), if we can find proteins with similar sequences and known structures (often called *the structure framework or template*), it is possible to predict the structure of the query with confidence using comparative modeling approaches (e.g., Sali and Blundell, 1993; Burke *et al*., 1999).

When no template can be detected via sequence similarity, protein fold–recognition methods are often employed for structure prediction. These are based on the observation that proteins of very different sequences, without recognizable sequence similarities, can have the same folds (Orengo *et al*., 2001). Even when a template is a remote homolog of the query sequence, it is still possible to use fold-recognition tools to generate a more accurate structure model.

Threading is a class of methods for protein fold–recognition. When the word was first coined by Jones *et al*. (1992), the original term was "optimal sequence threading", but soon shortened to "threading". The query sequence will be "threaded" onto backbones of structure templates. Contact potential and other scoring schemes are then applied to evaluate the proposed model.

In this process, it is assumed that the backbones of the structures are rigid and only the side chains of amino acids are different between the query and the template. However, given the low sequence similarities between queries and templates, even with the same fold, the backbone structures will probably have large differences from each other, and side chains of most residues will be different. Threading programs cannot therefore use contact potentials or pseudo-energy functions that require detailed structure descriptions or coordinates of all atoms. Often scoring schemes are applied just on pair interactions between residue centers or residue side chain/backbone centers. Instead of using physical energy functions of atom interaction, empirical energy scores can be derived on the basis of the observed associations of amino acids in known protein structures. Contacts that are more frequently observed in known structures will have higher scores (for reviews, Sippl, 1995; Jones and Thornton, 1996; Lazaridis and Karplus, 2000; Lin *et al*., 2002).

Ungapped threading is the simplest form of threading. Insertion and deletion of residues are disallowed in alignment. The starting point of matching determines the alignment and the quality of the model. The method is obviously the fastest. However, without the gaps the sensitivity of the method is not suitable for the recognition of distant fold relationships.

Standard dynamic programming algorithms for pairwise sequence alignment can be employed for matching structure templates and query sequences. From known structures, it can be estimated which amino acids are preferred in certain structure environments. Alternatively, which amino acids are often aligned to residues with certain structure environments can be observed from available structure alignments. Having these statistics, PSSM (Position Specific Scoring Matrix) profiles can then be derived from structure templates using the structure environments of their residues. Sequence alignment algorithms can be easily adapted for the aligning of profiles and sequences. New profile-based methods often integrate other features, including predicted secondary structure and residue exposure and sequence profile from PSI-Blast searching and multiple sequence alignment. These programs are fast. Their speed is comparable to sequence alignment programs. By including structural information, they achieved good performances, proved in various experiments (Bowie *et al*., 1991; Rice and Eisenberg, 1997; Rost, 1997; Jones, 1999; Kelley *et al*., 2000; Shi *et al*., 2001; Sippl *et al*., 2001).

However, the independent assumption of standard dynamic programming algorithms is incompatible with the contact potentials for threading. When aligning two sequences (or a profile with a query sequence) using dynamic programming algorithm, it is assumed that each aligned residue pair is independent of others. Contact potential scores are decided by the aligning of residues with structural contacts. Dynamic programming algorithms cannot be directly used with these scoring schemes.

Jones *et al*. (1992) used the double dynamic programming algorithm to find the optimal alignment. The algorithm was originally designed for protein-structure alignment (Taylor and Orengo, 1989). A second level of dynamic programming algorithm was introduced for the scoring of nonlocal spatial interactions between residues. The algorithm includes more aligned residue pairs through iterations, till the completion of the alignment. Similar heuristic or exhaustive approaches had been developed later using techniques such as recursive dynamic programming (Thiele *et al*., 1999), Gibbs sampling algorithm (Bryant, 1996), and other heuristic algorithms (e.g., Taylor, 1997; Huber *et al*., 1999; Xu and Xu, 2000). These programs, which fit sequences directly onto templates using contact potentials, are sometime considered the “real” threading methods, compared to the profile-based 3D-1D matching programs, which are essentially augmented sequence alignment methods. The “real” threading programs are much slower and require more computing resources, which make them unfit for genome scale investigations. It is worth noting that few of them use contact potentials alone: secondary structure matching scores, sequence profile, and solvent potentials are often combined into the scoring schemes for better evaluation of models.

The CASP (Critical Assessment of Techniques for Protein Structure Prediction) exercise is a widely recognized examination of protein structure–prediction methods (Moult *et al*., 2001). Participants predict protein structures using sequences

the CASP organizers collected from structure solvers before the native structures were published. More objective assessment can be made since the coordinates of structures are not available in any public databases in the process of prediction. At the first CASP, the original THREADER program by Jones and coworkers correctly recognized 8 out of 11 queries, and was marked as one of the best fold-recognition tools. Later, with advanced techniques and larger databases of structure templates, profile-based programs have gained more success, especially when templates and query sequences share some revolutionary relationship (Sippl *et al*., 2001).

Because of the difficult task of detecting and aligning queries to remotely related templates, alignments produced via threading methods are often of poor quality. The assumption of rigid backbones also limits accuracy. Manual inspection and modification using comparative modeling approaches is often needed to generate a good structure model using threading alignments. However, when there is no obvious evolutionary relation between the query sequence and templates, threading is one of the very few methods that can predict the fold.

Threading is a template-based protein fold–recognition method. With the increasing number of known folds, improved contact potentials will become available, and template libraries will have better coverage. As the CASP exercise continues, it will be interesting to follow the progress of threading techniques and their use in genome annotation.

CASP

Krzysztof Fidelis
Lawrence Livermore National Laboratory, Livermore, CA, USA

1. Main goals

Elucidation of protein structure plays a major role in transforming the biological sciences from the descriptive analysis of organisms to the understanding of many processes at the molecular level. Nevertheless, even with rapid advances in crystallography and NMR spectroscopy, our knowledge of protein structures lags far behind our knowledge of sequences. Therefore, for many identified proteins, no structural data are available. The primary goal of CASP is to address the question of how effectively computational methods can help narrow this information gap. By providing critical assessment, CASP aims at identifying which methods work and which do not, where the barriers to progress remain, and how to best formulate the goals for future methods development.

2. Rigorous testing of prediction methods

Historically, bona fide testing of prediction methods has been difficult to implement because of the small number of unique structures being solved. With the considerably increased number of new structures, it was possible to design a prediction experiment in which the answers are not initially known but become available in a reasonable time. CASP follows the principles of blind prediction and independent evaluation of the results. Initially, essentially only the sequence information on structures about to be solved is released to predictors. These data are made available through the CASP website or sent directly to registered servers. Next, the participating research groups deposit models of target structures prior to the public release of experimental results. Groups operating prediction servers comply with tighter 48-h deadlines. Finally, the models are compared with structures derived experimentally, using numerical evaluation techniques and human assessment, and a meeting is held to discuss the significance of the results. This approach offers several advantages over assessments made previously. In addition to a truly predictive mechanism, CASP allows testing multiple prediction methods simultaneously and side-by-side comparisons of the results obtained on the same set of prediction targets. The selection of targets is quite arbitrary, removing any possibility of bias that could have been introduced if targets were selected by predictors themselves.

And finally, the assessments are made with a uniform set of evaluation methods, and verified by independent assessors.

3. Community involvement

CASP invites independent assessors to evaluate the quality of the received predictions and to assess the state of the art. Assessors are provided with numerical analysis data generated using approved methods but may also use their own evaluation techniques. The experiment itself is shaped by all the predictors getting together at the biannual CASP conferences and by consultancy groups of veteran CASP participants. The issues involve CASP policy and any major changes or extensions of the CASP process. In addition, since CASP5 in 2002, the FORCASP website (**www.FORCASP.org**) provides a forum where members of the prediction community may discuss the various aspects of the CASP experiment.

4. CASP Prediction Center

Since 1996, the Prediction Center at Livermore handles all the data needs of CASP, including (1) information about the experiment and timings on all targets; (2) verification of target and prediction data; (3) evaluation of predictions; and (4) results analysis, presentation, and visualization. With the need for obtaining a comprehensive picture of prediction quality and progress between assessments, CASP provided strong impetus for the development of many new evaluation, analysis, and visualization techniques. The demand for assessment is growing rapidly. In the recently concluded CASP6, approximately 200 research groups from over 20 countries have participated submitting over 40 000 predictions.

5. Categories of prediction

The final result of a structure prediction largely depends on how much information from the already known structures can be used. At one extreme, models competitive with experiment can be produced for proteins with sequences very similar to those of known structures. At the other, models for proteins with no detectable sequence or structure relationship to one of the known structures are still at best very approximate. Historically, reflecting on how extensively models could be based on knowledge of other structures, targets have been divided into three broad categories: comparative modeling, fold recognition, and prediction of new folds. Comparative or homology modeling relies on the fact that for all pairs of natural proteins so far encountered, a clear sequence relationship implies similar structures. Thus, the structure of a homologous protein can to a large degree guide generating a model of a new one. Fold recognition takes advantage of the fact that protein structure is much more strongly conserved than sequence. Increasingly, new structures deposited in the Protein Data Bank turn out to have folds that have been seen before, even though there is no obvious sequence relationship

between the related structures. The goal is to identify these structural relationships in cases in which the sequence signal is either weak or does not exist. Over time, the boundary lines between these two categories have become blurred, and finer grained intracategory distinctions have begun to appear. In the recent CASP6 (2004), prediction targets were divided into two categories, those with detectable sequence homology to known structures, and those characterized by only structural similarity or constituting entirely new folds. In CASP, models are accepted as sets of 3D coordinates and alignments to known structures. Also accepted are predictions of residue–residue contacts, predictions of disordered regions, and most recently structure-based predictions of function.

6. Evaluation of predictions

Any approach to the evaluation of model structures faces several challenges. First, it must provide not only an overall picture of model quality but also information about specific areas, allowing to identify precisely where development is most needed. Second, it should handle well predictions submitted on targets ranging in difficulty and resulting in different levels of accuracy or providing different levels of detail. Finally, as evaluation methods are critical in comparing the performance of different prediction groups, such an approach must be agreed upon and respected by the community. Details of the evaluation techniques developed for CASP can be found in the special issues of Proteins (1995).

7. Progress over CASPs

What kind of progress, if any, can be seen over the six CASP experiments held so far (1994–2004)? To answer this question is not particularly easy as assessments have to be performed over separate sets of prediction targets. Nevertheless, some trends are quite clear (Venclovas *et al*., 2003). First of all, there has been a steady progress over all six CASPs, amounting to a gradual "pushing of the envelope" rather than a breakthrough. Second, progress is most visible for targets of medium difficulty, corresponding to the area of remote homology modeling through (homologous) fold recognition, that is, where sequence signal is weak but still recognizable. Progress in comparative modeling, particularly in the case of relatively high sequence identity to a known template, proved to be rather slow. This is particularly disappointing as more and more of structure space is explored experimentally, both by conventional structural biology and more aggressively by structural genomics, and progressively more modeling targets will fall into this category. Finally, progress in the most difficult area of structure prediction has been visible but the results are quite different for targets with identifiable structure similarity to a known template and for new folds. In the first case, a significant majority of targets can be modeled to a degree where at least the fold is correctly identified; in the second, a similar result is achieved for only very few small targets.

Short Specialist Review

Molecular simulations in structure prediction

Franca Fraternali

National Institute for Medical Research, London, UK

Jens Kleinjung

Vrije Universiteit, Amsterdam, The Netherlands

1. Introduction

Molecular simulations allow us to study properties of many-particle systems and, in particular, to extract those properties that are not easily accessible to experimental techniques (Frenkel and Smit, 1996). If we were to use the physicist approach, we have to admit that the basic laws of nature have the unpleasant feature to be expressed in equations that cannot be solved exactly (analytically), except for few cases. Even the description of the motion of a three-body system by means of the simple laws of Newtonian mechanics is analytically intractable. Computer simulations, on the other hand, use a number of algorithms that allow us to calculate properties of many-particles systems (more than 100 000 atoms) at the required degree of accuracy. All molecular simulations to which we will refer are based on the assumption that classical mechanics can be used to describe the motions of atoms and molecules. Physics-based force fields at different levels of accuracy are generally used to describe the topology and geometry of molecules (van Gunsteren and Berendsen, 1990).

On the other hand, Bioinformatics tools allow us to analyze and rationalize the information content of biological systems and, from the acquired knowledge, to extrapolate and predict molecular properties that are not yet experimentally available. Therefore, in terms of logical strategies, molecular simulations use the inductive argument to infer knowledge, while Bioinformatics uses a deductive strategy; they can be seen as working synergically for the aim of filling the gaps of current experimental knowledge. Computational biology embraces both approaches, and experience reveals that both are indeed necessary to shed light on the complexity of biomolecules.

Since the genomic projects have started their proliferation of sequences, the so-called sequence gap (the difference between the number of known sequences and the known protein 3D structures) has become one of the most prominent challenges in biology. In particular, structural genomics initiatives address the

investigation of the native fold of sequenced proteins as a fundamental step to a complete understanding of their biological function. Experimental techniques such as NMR and X-ray crystallography are very effective in providing atomic resolution structures of a large number of proteins, but large-scale initiatives of high-throughput structure determination are still at a different pace compared to genomic sequencing projects.

Until now, all structure prediction methods still suffer in accuracy and are not yet reliable enough to compete even with available experimental low-resolution structure determination methods. If one could predict the topology at a low-resolution level (3–6 Å) and use molecular simulations to refine the atomic details of the structure, the sequence gap could be filled more rapidly and be useful in the assignment of function. The bottleneck of such a procedure is that long simulations times are required with conventional MD simulations in order to refine accurately misfolded structures (Fan and Mark, 2004).

In this article, we review some of the recent efforts in the fields of structure prediction and molecular simulations, with the common aim to efficiently contribute to large-scale structural genomics initiatives.

2. Structure prediction

Structure prediction projects for the modeling of large proteins (Amodeo *et al*., 2001; Fraternali and Pastore, 1999) and entire genomes have been performed (Fischer and Eisenberg, 1997; Sanchez and Sali, 1998), and genome annotation has been shown to benefit from the use of structural homology information (Mayor *et al*., 2004). The qualitative progress in structure prediction methods is regularly assessed in the CASP experiments (Venclovas *et al*., 2001).

The field is traditionally separated into three disciplines, depending upon the level of identity between the query sequence and sequences of template structures: (1) comparative modeling (>30% sequence identity), (2) fold recognition or threading (<30% sequence identity), and (3) ab initio folding (no template). Independent of this classification, benchmarks show that the quality of the predicted structure, given as root mean square deviation from the native structure, decreases exponentially with decreasing sequence identity, that is, from about 2 Å at 95% to >5 Å below 25% identity (Contreras-Moreira and Bates, 2002). Even at relatively high sequence identity of about 50–60%, predicted structures achieve on average only medium resolution (∼3 Å) (Vitkup *et al*., 2001).

The deviation of predicted structures from their native counterpart has chiefly two reasons: alignment errors and the template structure approximation. Matching a sequence onto a template structure is a computationally hard problem (Lathrop, 1994; Kolodny and Linial, 2004), which is generally solved using heuristic approximations that lead frequently to suboptimal solutions, in particular for difficult alignments of distant homologs. The template structure approximation is due to the simple fact that two homologous structures are similar but usually not identical. Taking one structure as the template for the other naturally causes deviations. Moreover, structure prediction programs use simplified potentials and heuristic methods to generate target structures at reasonable computational expense.

Therefore, subsequent refinement is imperative to evolve the modeled structure toward the native conformation.

3. Conformational sampling

The "sampling problem" is a well-known obstacle in molecular simulations of biomolecules, and it is particularly relevant for endeavors to detect the native fold. It is primarily caused by the enormous dimension of the conformational space, which is the collection of all accessible internal coordinate combinations. The backbone of an average size protein has about 10^{100} degrees of freedom, far beyond our systematic searching capabilities. Fortunately, biological evolution has selected for biological macromolecules that adopt a distinct fold, so that in many cases conformational sampling can be restricted to a subspace around a limited number of template folds.

However, the energy profile of a biological macromolecule with respect to internal motion is rugged, with barriers above the background energy kT between neighboring conformers. Thermal fluctuations are rarely high enough to drive the system over these barriers, and energy minimization calculations lead to local minima instead to the global minimum. Therefore, structure prediction methods use Monte Carlo protocols to assemble a large variety of low-resolution conformers, from which the best ones are chosen for further calculations (Simons *et al*., 1997). Approaches to overcome the sampling problem in refinement by molecular simulations are discussed in the last paragraph.

4. Identification of the native state

The central paradigm of structure prediction and refinement by molecular simulations is the identification of the native structure as the conformer at the global free energy minimum, or alternatively at the probability maximum. The underlying thermodynamic principle is the notion that a system (here a macromolecule in solution) in weak contact with a thermal bath evolves spontaneously to the state of minimal free energy (we use here the more common notation of the free enthalpy G). Thus, successful structure prediction and refinement tools need a target function that discriminates effectively between native and nonnative folds (Park *et al*., 1997; Mirny and Shakhnovich, 1998). The free enthalpy of a protein can be decomposed into the intramolecular van der Waals and electrostatic contributions and an additional solvent term:

$$\Delta G = \Delta G_{\text{vdW}} + \Delta G_{\text{ele}} + \Delta G_{\text{sol}} \quad (1)$$

However, in computer simulations the entropic component of the free enthalpy is often neglected, leading to a description in terms of intramolecular enthalpy:

$$\Delta G \simeq \Delta H_{\text{vdW}} + \Delta H_{\text{ele}} + \Delta G_{\text{sol}} \quad (2)$$

Intramolecular enthalpies are calculated as the sum of all pairwise (and sometimes triple-wise) atomic interaction energies. These energies are based on carefully

parametrized interaction functions, most importantly the Lennard–Jones potential for van der Waals interactions and the Coulomb potential for electrostatic interactions. The ensemble of parametrized interaction functions defines a “force field”. We distinguish between two types of force fields: physics-based force fields and knowledge-based force fields.

Physics-based force fields are derived from quantum-molecular or molecular dynamics simulations of small molecules. Prominent examples for physics-based force fields are AMBER (Wang *et al*., 2000), CHARMM (Brooks *et al*., 1983), and GROMOS (van Gunsteren *et al*., 1996). Specific energy parameters have been designed for RNA molecules, owing to their particular intramolecular interactions and secondary structure patterns (Freier *et al*., 1986; Jaeger *et al*., 1989).

Knowledge-based or statistical force fields are derived from probabilities of states of known structures (Bowie *et al*., 1991; Jones *et al*., 1992; Madej *et al*., 1995; Huber and Torda, 1999; Lu *et al*., 2003). The transformation function between the (observed) probability of a state (for example the distance between two residues i and j) and the associated interaction energy is the Boltzmann term:

$$p(X_{ij}(r)) = \mathrm{e}^{-\frac{E(X_{ij}(r))}{kT}} \tag{3}$$

where $X_{ij}(r)$ is the state X as a function of the distance r between i and j, $E(X_{ij}(r))$ is the interaction energy (potential) associated with $X_{ij}(r)$, k is the Boltzmann constant, and T is the temperature. Transformation of equation (3) yields the knowledge-based potential

$$E(X_{ij}(r)) = -kT \log p(X_{ij}(r)) \tag{4}$$

often referred to as “potential of mean force”, because the interaction energy represents a collection of states.

Physics-based force fields model the physical reality starting from first principles, which renders them suitable for simulating accurately a wide range of molecules. However, early force fields were based on relatively small training sets, so that knowledge-based force fields were superior in describing specific classes of molecules at considerably reduced computational cost. On the other hand, knowledge-based potentials are by definition biased toward the training set, yielding questionable results for molecules with features far outside the range of those in the training set. Over the last decades, continuous refinement has improved the performance of physics-based force fields to a level equaling knowledge-based potentials (Lazaridis and Karplus, 1999a).

As an alternative to the conversion of state probabilities to energies as exemplified by equations (3) and (4), evaluation of predicted structures can be performed entirely in probability space, in which case the target function is the total probability maximum instead of the free energy minimum. It is common practice in Bioinformatics not to use the raw observed probabilities of states, but to convert those to a scoring function by normalization and transformation to a logarithmic scale:

$$S(X_{ij}(r)) = \log \frac{p(X_{ij}(r))}{p(X_{ij}^{\mathrm{rand}}(r))} \tag{5}$$

Here, $p(X_{ij}^{\text{rand}}(r))$ is the probability of observing state $X_{ij}(r)$ in a random set of conformers, which normalizes the observation probability with the expectation probability. The score S is often referred to as "log odds" score or "relative entropy", and it has the property to be additive.

If the logarithm is taken as $\log_2$, the score S in equation (5) is equivalent with the amount of information in units of "bit" that is gained when state $X_{ij}(r)$ is observed.

5. Refinement by molecular simulations

Structure refinement has originally been developed for experimental structure determination, that is, in NMR or X-ray resolution of proteins and DNA/RNA molecules. Experimental data are converted into distance restraints and combined with a classical molecular force field. Shortly after the invention of restrained molecular dynamics for (experimental) de novo structure calculation of proteins (Brünger *et al*., 1986), the "distance-geometry" method was developed, in which the classical force field was replaced with a simplified interaction function to increase computational speed, and simulated annealing was performed to enhance conformational sampling (Nilges *et al*., 1988). These developments led to the structure refinement program XPLOR (Brünger, 1992). Another approach was implemented in the program DIANA, where conformational sampling starts from random conformations and converges to the final structure by target function minimization in angular space (Güntert and Wüthrich, 1991).

A different situation emerges with regard to the refinement of predicted structures. The accuracy of generated conformers relies entirely on the precision of the force field and the efficiency in sampling around the native state. The detailed physics-based force fields and the associated extensive interaction calculations in molecular dynamics provide a much finer resolution than structure prediction methods and thus should be superior in defining the native state. Reports about the success of molecular dynamics in structure refinement imply that simplified representations or limited sampling fail to improve the predicted structure (Schonbrun *et al*., 2002), but carefully defined simulations can yield significantly better conformers (Lee *et al*., 2001; Flohil *et al*., 2002; Fan and Mark, 2004).

However, long simulation times are prohibitive for large-scale structure prediction applications. An effective means to shorten simulation time without sacrificing the solvent contribution to the free energy is the usage of implicit solvation (Fraternali and van Gunsteren, 1996; Lazaridis and Karplus, 1999b Ferrara *et al*., 2002). Numerous protocols have been developed to improve the sampling efficiency of molecular simulations. The extension of molecular dynamics to four dimension allows the molecule to bypass 3D barriers (van Schaik *et al*., 1993), and "local elevation" disfavors already visited conformations in order to enhance exploration of conformational space (Huber *et al*., 1994). Leap dynamics is a combination of Monte Carlo and molecular dynamics methods, in which limited conformational changes are induced and the new conformer performs a local search (Kleinjung *et al*., 2000; Kleinjung *et al*., 2003). An example for a purely stochastic protocol is the optimal-bias Monte Carlo method, in which the global energy minimum is searched within the internal coordinate space (Abagyan and Totrov, 1999).

Systematic studies about the predictive power of these refinement methods in combination with large-scale structure prediction projects should be undertaken to provide high-resolution models for the majority of sequenced biomolecules.

Short Specialist Review

Protein structure comparison

Liisa Holm
University of Helsinki, Helsinki, Finland

1. Introduction

Improved methods of protein engineering, crystallography, and NMR spectroscopy have led to a surge of new protein structures deposited in the Protein Data Bank (PDB) (*see* Article 71, **The Protein Data Bank (PDB) and the Worldwide PDB http://www.wwpdb.org**, Volume 7). At the end of 2004, the PDB contained over 28 000 protein structures, and the structural genomics initiative aims to provide a structure for each major protein family within a decade. This wealth of data needs to be organized and correlated using automated methods. Nearly all proteins have structural similarities to other proteins. General similarities arise from principles of physics and chemistry that limit the number of ways in which a polypeptide chain can fold into a compact globule. Evolutionary relationships result in surprising similarities. Because structure tends to diverge more conservatively than sequence during evolution, structure alignment is a more powerful method than pairwise sequence alignment for detecting homology and aligning the sequences of distantly related proteins. In favorable cases, comparing 3D (three-dimensional) structures may reveal biologically interesting similarities that are not detectable by comparing sequences and may help infer functional properties of hypothetical proteins.

2. Overview

Automatic methods enable exhaustive all-against-all structure comparisons. As a result, each structure in the PDB can be represented as a node in a graph in which similar structures are neighbors of each other and structurally unrelated proteins are not neighbors. Clustering the graph at different levels of granularity removes redundancy and aids navigation in protein space. At long range, the overall distribution of folds (*see* Article 69, **Complexity in biological structures and systems**, Volume 7) is dominated by secondary structure composition (for example, all-alpha or alternating alpha/beta). At intermediate range, clusters are related by shape similarity that does not necessarily reflect similarity of biological function (for example, globins and colicin A). At close range, clusters represent protein families related through

strong functional constraints (for example, hemoglobin and myoglobin). Evolutionary relationships can be recovered by searching for continuous neighborhoods, since evolution is a diffusive process in protein space (Maynard-Smith, 1970).

In order to identify natural groupings of any set of objects, one needs a measure of distance or similarity. Structure comparison programs derive a structural alignment, which maximizes similarity or minimizes distance (Brown *et al*., 1996). The alignment defines a one-to-one correspondence of amino acid residues (sequence positions) in two proteins. This is analogous to sequence alignment (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7) except that the notion of (dis)similarity is much more complex between 3D objects than between linear strings (Figure 1). For example, the conformation of a point mutant differs from the wild-type protein only locally and may only be a few tenths of an Angstrom. Much larger deviations are observed in pairs of homologous proteins; with increasing sequence dissimilarity, small shifts in the relative orientations of secondary structure elements accumulate and reach several Angstroms and tens of degrees. At the largest evolutionary distances, only the topology of the fold or folding motif is conserved; topology here means the relative location of helices and strands and the loop connections between these. Deviations can be even larger and qualitatively different when structural similarity is the result of convergent rather than divergent evolution. In particular, convergent evolution may result in similar 3D folds that differ in the topology of loop connections.

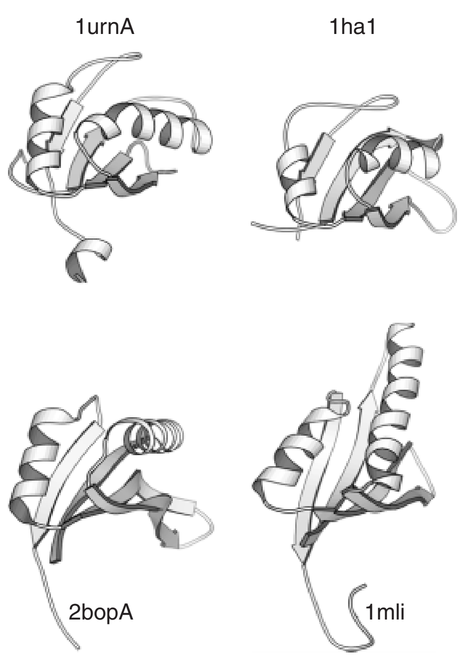

Figure 1 Structural neighbors of u1a spliceosomal protein (top left) from closest to more distant: hnRNP A1 ($Z = 10$, top right), DNA-binding domain of papillomavirus E2 ($Z = 5$, bottom left), muconolactone isomerase ($Z = 2$, bottom right). 1mli has the same topology even though there are shifts in the relative orientation of secondary structure elements

The modular architecture of proteins presents another complication. Large proteins can be decomposed into semiautonomous, globular folding units called domains. Domains are often evolutionarily mobile modules and may carry specific biological functions. Because a common domain may be surrounded by completely unrelated domains, most structure comparison methods search for local similarities.

3. Measures of structural similarity

Most programs for protein structure comparison quantify the quality of the alignment based on geometric properties of the set of points (C-alpha positions) or vectors representing the secondary structure elements. It is noteworthy that there is no consensus on the best measure of similarity. One criterion for a useful measure is that it should yield stronger similarity to presumably homologous than to analogous folds, in agreement with evolutionary classifications based on visual inspection of protein structures.

Similarity measures are usually defined in terms of comparing either inter- or intramolecular distances. The first approach, in essence, superimposes each protein so that corresponding points are as close together as possible. This method, therefore, needs to first uncover the rigid transformation that optimally positions both proteins relative to each other. An early suggestion of a structural distance metric was based on the surface area enclosed by the C-alpha traces of two superimposed structures. The most conventional measure is the root-mean-square deviation (RMSD) of the corresponding atoms:

$$RMSD = \sqrt{1/N\,\Sigma(|\mathbf{x}(i) - \mathbf{y}(i)|^2)} \tag{1}$$

where the summation is over all N corresponding atoms i and $\mathbf{x}$ and $\mathbf{y}$ are the coordinates of the atoms. RMSD is sensitive to outliers and does not have a unique optimum if the set of corresponding atoms can be made smaller or larger. Many variants of RMSD with a smoother penalty for ill-fitting atoms have been proposed. The most common formulation of an objective is that of accommodating the largest possible number of equivalent points within small deviations in position, typically less than 2 to 3 Å.

The structural core that can be superimposed as a rigid body at low RMSD shrinks with increasing evolutionary distance. For example, the (beta/alpha)$_8$-barrel is a frequent topology but the cross section of the barrel varies from circular to elliptical. This leads to high root-mean-square distance deviations in rigid-body 3D superimposition. To account for conformational flexibility, an edit distance like measure has been proposed that selects very well fitting rigid blocks with a penalty for twists around pivot points (hinges) introduced in the reference protein. Distance matrix comparison identifies both local similarities and tolerates plastic deformations between more distant parts of the molecules with the same topology. The distance matrix representation of protein structure is independent of coordinate frame, but contains more than enough information to reconstruct the 3D coordinates, except for overall chirality, by distance geometry methods. Some intramolecular-distance-based methods compare the respective distance matrices

of each structure, trying to match the corresponding intramolecular distances for selected aligned substructures. One definition of similarity has the form

$$\text{Dali-score} = \Sigma\Sigma\left(\frac{\alpha - \Delta}{\langle D\rangle}\right)\exp\left(\frac{\langle D\rangle^2}{\beta^2}\right) \tag{2}$$

where the summation is over all pairs of C-alpha atoms in the common substructure, Δ is the difference between the two intramolecular distances, $\langle D\rangle$ is the average of the two intramolecular distances and α and β are arbitrarily defined constants (Holm and Sander, 1996). A variety of other functional forms of a sum-of-pairs score are in use.

The statistical significance of an observed similarity is typically determined empirically against a background distribution of similarities observed between randomly selected pairs. Statistical models of structural evolution similar to the Dayhoff model for sequences have also been proposed.

4. Search algorithms

Given a measure of similarity or distance, the algorithmic problem is to find the set of corresponding points in two structures that optimize this target function. Just as there is much latitude in the formulation of the structure comparison problem, many different types of optimization algorithm have been employed. Similarity measures of the sum-of-pairs form and subgraph isomorphism formulations of the structure comparison problem belong to the NP-complete class of problems, and one has to resort to heuristics for practical algorithms. Heuristic approaches do not aim for provably correct solutions, gaining computational performance at the potential cost of accuracy or precision. Many programs use a hierarchical approach, where promising seeds for alignment are identified using local criteria based on dynamic programming, distance difference matrices, maximal common subgraph detection, fragment matching, geometric hashing, unit vector comparison, or local geometry matching. The initial set of correspondences is then optimized globally using methods such as double dynamic programming, Monte Carlo algorithms or simulated annealing, a genetic algorithm, or combinatorial searching. Recently, it has been proved that brute-force exhaustive scanning of the six degrees of freedom from rotations and translations in rigid-body superimposition leads to a polynomial-time approximation algorithm for the problem of determining the maximum number of C-alpha atom pairs that can be superimposed within a given RMSD at a given error. However, this solution is too computationally demanding for practical application.

5. Related problems

Biologists are interested in comparing a newly solved structure against all known structures in the PDB. For database searching, fast indexing filters have been developed. These methods compute a signature function from the geometrical properties,

with the idea that very similar structures will obtain similar values of the function. Highly similar structures can thus be identified quickly and efficiently. Database searching can benefit from a hierarchical strategy that uses initially fast filters to detect identity or strong similarity to known structures, and applies slower but more sensitive methods to the nontrivial cases.

Structural alignment algorithms detect similarities between globular folds that are composed of many secondary structure elements. Recurrent structural motifs are even more abundant on a smaller scale than domains. Complete protein structures can be approximately reproduced by concatenating pieces from relatively small fragment libraries. Functional sites may be defined by the geometry of a few essential side chains, and specialized tools have been developed for finding this type of motifs (*see* Article 35, **Measuring evolutionary constraints as protein properties reflecting underlying mechanisms**, Volume 7). Defining protein function through its interactions with other molecules has also generated interest in the comparison of molecular surfaces.

6. Applications

Many methods for pairwise protein structure alignment and database searching have been proposed and are available on the World Wide Web. The most commonly used server is Dali, hosted by the European Bioinformatics Institute (**http://www.ebi.ac.uk/dali**). Precomputed hierarchical classifications are likewise available. They organize folds in structural dendrograms (CATH and Dali database) or a taxonomic classification using a combination of structural and evolution information with a good deal of human expertise (SCOP). The integration of structural alignments and sequence comparisons is useful, for example, to identify conserved functional motifs. Structure comparison also provides benchmarks for assessing the accuracy and sensitivity of sequence comparison methods (*see* Article 73, **CASP**, Volume 7).

Short Specialist Review

Secondary structure prediction

Ching Wai Tan and David T. Jones
University College London, London, UK

The prediction of protein secondary structure from amino acid sequence has been attempted since the late 1950s. It is a natural intermediate step to uncovering the tertiary structure of a sequence because discovering the local conformations of regions in the protein sequence precedes any informed guesses of the sequence's 3D fold. Secondary structure prediction is also significantly easier because it is essentially the prediction of 1D structural data from sequence (assignment of local state to each residue), as opposed to tertiary structure prediction, which has the goal of predicting 3D coordinates from sequence.

The secondary structure of a subsequence forms during the folding process because it is energetically favorable for that particular region of the sequence to adopt such a local conformation. Electrostatic charges belonging to C=0 and N−H groups in the backbone chain interact with each other to form hydrogen bonds. As a result of hydrogen bonds forming between the C=0 and N−H groups, two possible regular local conformations exist, namely, the helix and the strand (Pauling and Corey, 1951). A helix forms when the C=0 group hydrogen bonds with an N−H group 3, 4, or 5 positions away along the backbone chain, and a sheet forms when the two participating hydrogen bonding groups are from two distinct subsequences far apart in the sequence. Irregular conformations do form between residues, and these are loosely regarded as loop conformations, which also include residues that do not form any hydrogen bonds at all.

Intuitively, we can visually inspect and assign, say, the helix state to a set of consecutive residues. However, an objective assignment of a conformation to each and every residue in the sequence is necessary to avoid ambiguity when it comes to secondary structure prediction. The Define Secondary Structure of Proteins (DSSP) program (Kabsch and Sander, 1983) gives a systematic and unambiguous definition of these secondary structural elements in terms of the presence and location of hydrogen bonds between C=0 and N−H groups in the protein sequence. A hydrogen bond is assigned when the net electrostatic force between the C=0 and N−H group is below -0.5 kcal mol^{-1}. In assigning secondary structure, DSSP defines two elementary conformations, namely, the n-turn, $n = 3, 4, 5$ T, and the bridge (B), depending on the locations of the two interacting C=0 and N−H groups within the sequence. Helices are built from two or more consecutive n-turns, and these can be the α-helix where $n = 4$ (H), 3_{10} helix where $n = 3$ (G) and π helix where $n = 5$ (I). Bridges can be parallel or antiparallel, depending on the direction of the

two participating subsequences. Continuous stretches of bridges form β-strands (denoted as E in the DSSP alphabet) and one or more β-strands form β-sheets.

Other methods for objective assignment of secondary structural state, such as STRIDE (Frishman and Argos, 1995), have been developed. The main aim of STRIDE is to attempt to model the expert knowledge of crystallographers in terms of secondary structure assignment. It assumes that, barring obvious errors and the usage of DSSP, the authors of PDB files use their expertise to correctly assign secondary structural information to the protein whose structure they have just solved. STRIDE operates on the assumption that hydrogen bonds alone are insufficient criteria for assigning secondary structural states to residues. It defines a formula that incorporates torsion angle and hydrogen bond information, and the parameters of this formula are empirically fitted to match the secondary structure definitions found in the PDB database. One drawback of DSSP is that it tends to split a long helix into two owing to missing hydrogen bonds in the middle in spite of its completely acceptable geometry. STRIDE can overcome this because in addition to looking at hydrogen bonding patterns, it also takes main chain torsion angles into account. Despite these improvements, DSSP still remains the popular method when it comes to assigning secondary structural states.

While the DSSP definitions of the eight types of secondary structural state are unambiguous and used for exact assignment of state to secondary structure prediction datasets, most secondary structure prediction methods are content to deal with only the three most common types, namely, helices, strands, and loops or coil. An exception to this is Baldi's SSPro8 (Pollastri *et al*., 2002) method, which strives to predict the eight possible DSSP states. This leads to the issue of reducing the 8 DSSP states to 3 states, prior to the actual usage of the prediction method and the training, if required, of the prediction method. Of course, if DSSP is not used and the secondary structural states found in the PDB files are taken to represent the correct assignments, there is no need for any reduction method whatsoever. However, if DSSP is used as the standard means for assignment, then the reduction issue is relevant. One 8-to-3 state reduction method is to assign G and H states to the helix state, B and E to the sheet state, and all others to the loop state. Another is to assign H to the helix state, E to the sheet state, and all others to the loop state. Barton and coworkers (Cuff and Barton, 1999) have demonstrated the effect of different 8-to-3 reduction methods on the accuracy of some secondary structural prediction methods to be minimal. Nevertheless, it is important to note that when comparing different secondary structure prediction techniques, if DSSP is used as the "gold standard", it is essential to ensure that the same 8-to-3 reduction method has been applied for all methods being evaluated.

Having discussed the issues of defining secondary structural states, we now discuss the evaluation of the accuracies of secondary structure prediction. The most common accuracy measure is the Q3 score. The Q3 score is the average of each Qi (i = helix, sheet, loop), where Qi is defined as the percentage of correctly predicted residues in state i to the total number of experimentally observed residues in state i. The numbers of residues in helices, strands, and loops in the database (testing datasets) are frequently not evenly distributed, with loops usually comprising the greatest proportion, and because we are usually more interested in the correct

predictions of helices and strands, it is important to be aware that the Q3 score can give an overoptimistic estimate of accuracy than might be expected.

The best prediction methods currently have Q3 scores of somewhere between 75 and 80%. However, the Q3 score does not tell the whole story regarding the accuracy of secondary structure prediction methods. Because the Q3 score focuses on per-residue accuracy, it neglects to evaluate the overall picture of how predicted secondary structure elements are correctly positioned across the sequence. For example, if one were to predict every residue in helix-dominated myglobin to adopt a helical conformation, an accuracy of 80% would be obtained. Of course, such an uninformative prediction would hardly be very useful in understanding the overall topology of myglobin.

Rost and coworkers (Rost *et al*., 1994; Zemla *et al*., 1999) proposed another accuracy measure for secondary structure prediction, known as the Segment OVerlap measure (SOV). SOV_i, for each i (i = helix, strand, loop), measures the extent to which the predicted segment of state i is identical to the experimentally observed structure. The SOV3 score is taken as the average of all SOV_i scores. It is recommended by Rost that both the Q3 and SOV3 scores are used for secondary structure evaluation, and this has been the case in all CASP experiments since CASP2. The CASP (Critical Assessment of Methods of Protein Structure Prediction) experiments are a biannual event since 1994 where participants compare their methods in order to determine which method produces the best results for secondary and tertiary structure prediction of recent experimentally solved proteins. A key aspect of CASP is that the details of the experimentally solved structures are withheld from the predictors until the end of the experiment. CAFASP (Critical Assessment of Fully Automated Structure Prediction) is a similar but independent event, run since 1998, that focuses solely on automatic evaluation of automated servers.

Now that we have looked at how secondary structure is defined and how predictions can be effectively evaluated, we now look at some commonly used approaches for secondary structure prediction. All sorts of algorithms have been proposed for secondary structure prediction over the past 40 plus years, and we limit our brief discussion here to knowledge-based techniques. For historical reasons, it is important to note some early pioneering prediction techniques such as the GOR method (Garnier *et al*., 1978) that made use of information theoretical techniques and the Chou and Fasman method (Chou and Fasman, 1974) that used a qualitative method, in the form of simple rules, to try to predict secondary structure. These techniques, which do not have high accuracies, nevertheless, paved the way for more sophisticated knowledge-based approaches such as the machine-learning-based techniques widely used today. Diverse multivariate methods such as discriminant analysis (Solovyev and Salamov, 1994), nearest neighbors (Salamov and Solovyev, 1995), and linear discriminant functions (King and Sternberg, 1996) have been exploited, but by far, the most popular machine-learning technique used in secondary structure prediction is that of neural networks (Jones, 1999; Rost and Sander, 1993; Rost and Sander, 1994), though recently, support vector machines (SVMs) have been successfully used as well (Ward *et al*., 2003). Perhaps owing to their popularity, neural network–based methods have generally yielded the best results in the literature, and numerous network architectures have been tried. For the widely used PSIPRED (Jones, 1999) and PHD (Rost and Sander, 1993) methods, feedforward

neural networks have proved sufficient, while SSPro (Pollastri *et al*., 2002) uses a recurrent network architecture.

In contrast to the earliest methods, which used just the target sequence itself, modern secondary structure prediction methods make use of multiple sequence alignments based on the given target sequence (Rost *et al*., 1994). Typically, this alignment is produced using PSI-BLAST (Altschul *et al*., 1997), which is considered one of the better methods for generating divergent sequence profiles. The rationale behind the successful use of multiple sequence alignments is that the alignments of homologous families can reveal evolutionary patterns such as highly conserved or highly variable regions. For example, conserved regions in a family of proteins may correspond to functionally important residues that are unlikely to have undergone significant changes over time. Of more relevance to secondary structure prediction is the observation that the most conserved hydrophobic regions in a protein tend to correspond to the hydrophobic core of the protein. In contrast to the core residues, the surface residues have few structural constraints and will typically exhibit a high degree of mutation within the family of proteins. Such information can be used to increase the accuracy of predicting secondary structural state. Current state-of-the-art secondary structure prediction methods such as PSIPRED and PHD all use multiple sequence alignment information as their inputs. PSIPRED uses PSI-BLAST profiles, intermediate outputs of the PSI-BLAST tool, to represent the alignment information, while PHD does its own calculation and alignment of multiple sequence information.

The current state-of-the-art secondary structure prediction methods have Q3 scores ranging from around 74 to 80%, with the exact measured accuracies varying for different test sets used. It is hard to pinpoint a particular method as being a hands-down winner as these methods have several common features, and also use different datasets for training purposes, which makes it hard for a fair comparison to be made. However, an indication of the best performing secondary structure prediction technique can be found in CASP4 held in 2000. Here the PSIPRED method achieved an average Q3 score of 80.6% across all 40 submitted target domains with no obvious sequence similarity to structures already present in PDB.

While CASP results are indicative of the performances of various prediction methods, the CASP experiments are run only once every 2 years, and it would be desirable to have an automated service to compare secondary structure predictions on a regular basis. Fortunately, such a service exists in the form of EVA (Rost and Eyrich, 2001), which is an automated secondary structure assessment server that attempts to evaluate the performances of several secondary structure prediction servers. (EVA actually does more; it evaluates comparative modeling and contact prediction techniques as well.) This implies that EVA can only evaluate prediction techniques that are automated in the form of servers. EVA runs several secondary structure prediction servers on recently solved protein structures and compares and presents the prediction results on-line. It also uses the following 8-to-3 reduction technique: HGI to the helix state, EB to the sheet state, and the others to the loop state. Some of the participating prediction servers are PSIPRED, PHD, JPred (Cuff *et al*., 1998), and SSPro. Apart from JPred, which uses a consensus-based approach, these methods make use of knowledge-based approaches, in the form of neural networks, that learn from input evolutionary information. Such commonality

between these methods is probably the reason why there is not much difference between them in terms of Q3 and SOV3 accuracies, as evaluated by EVA.

The field of secondary structure prediction has reached a level of maturity where consistent Q3 and SOV3 accuracies of beyond 80 to 85% are arguably difficult to achieve. One possible reason is that the formation of secondary structure of a sequence segment is in part due to long-range interactions within the protein sequence and these are extremely difficult to take into account. To completely model these interactions, the full tertiary structure of the protein would need to be predicted, which of course creates a "chicken and egg" situation if secondary structure information is being used to model protein tertiary structure. The remaining accuracy gaps are therefore probably quite difficult to close using sequence information alone. In fact, the CASP community has informally reached a decision to drop the evaluation of secondary structure prediction techniques from the ongoing CASP6.

The challenge now regarding secondary structure is less of improving the accuracy of prediction techniques; rather it is more of how secondary structure prediction techniques can aid in constructing the 3D fold of a target protein sequence. For instance, given a particular prediction result, the question of how secondary structural elements can pack together in a compact manner remains unclear in protein structure prediction.

Short Specialist Review

DNA/protein modeling

Richard Lavery
Institut de Biologie Physico-Chimique, Paris, France

1. DNA structure and dynamics

How DNA interacts with proteins and is packed within the cell depends not only on its 1D sequence, but also on its 3D structure and on its mechanical properties (expressed through thermal fluctuations at room temperature). Experimental results have confirmed that both of these properties can vary along the length of the DNA molecule as a function of its base sequence. Computer modeling, using appropriate atomic interaction potentials, can help in predicting DNA structure and in simulating its thermal dynamics.

Atomic scale simulations of DNA have progressed greatly over the last decade, and it is now possible to simulate the behavior of oligomers containing 20–30 bp over nanosecond timescales (allowing for motions such as helix bending and twisting, sugar repuckering, etc.). Improved electrostatics, better parameterization, and faster computers have all played a part in this progress (Orozco *et al*., 2003). In the hope of predicting sequence effects on duplex DNA, extensive molecular dynamic studies are now being carried out on oligomers containing all 136 tetranucleotide sequences. These simulations will hopefully refine current models limited to di- or trinucleotide steps (Beveridge *et al*., 2004a). Simulations have already helped to understand the origins of intrinsic DNA curvature (Beveridge *et al*., 2004b) and how base sequence can change the mechanical properties of the double helix (Lankas, 2004). A number of specific DNA deformations (stretching, twisting, A-B transitions, etc.) have also been modeled, as well as local perturbations such as base-pair opening (Giudice and Lavery, 2003). Simulations are being used to design the modified oligonucleotides needed to block gene expression by binding to single-stranded RNA or double-stranded DNA targets and to study the structure and stability of quadruplex DNA, which has become an important target in cancer therapy (Read *et al*., 2001; *see also* Article 65, **Complexity of cancer as a genetic disease**, Volume 2).

2. Protein-DNA recognition

Identifying protein-binding sites is an increasingly important component of genome analysis and is essential for understanding gene regulation (*see* Article 19, **Promoter**

prediction, Volume 7 and Article 22, **Eukaryotic regulatory sequences**, Volume 7). Although experimental binding assays can yield consensus sequences (or weight matrices) that are sufficient in many cases, some proteins, and notably transcription factors, are difficult to characterize in this way because they bind to a broad range of sequences. Despite experimental progress, see, for example, (Roulet *et al*., 2002), isolating and identifying the DNA binding sites for a rapidly growing catalog of proteins will become increasingly difficult and theoretical approaches are needed.

In recent years, structural and thermodynamic data have both indicated that the formation of specific protein-DNA complexes cannot be understood in terms of a collection of pairwise interactions between amino acid side chains and nucleic acid bases. In many cases, such "direct" recognition is supplemented by "indirect" recognition, which relies on the sequence-dependent properties of the double helix. Indirect recognition remains difficult to characterize experimentally since it can involve structure, mechanics, and dynamics and, as discussed above, our understanding of these properties as a function of base sequence is still limited.

An analysis of complexes of known structure has helped in defining at least the structural component of indirect recognition by deriving the energy necessary to deform the target DNA during complex formation. Such analyses have shown that the total free energy of complexion (typically of the order of 40 kJ mol^{-1}) results from the compensation of many large terms, which, beyond the interacting macromolecules themselves, also involve the surrounding solvent counterions (Jayaram *et al*., 2002; Zakrzewska, 2003).

Despite the size of protein-DNA complexes, it has also been possible to carry out a limited number of molecular dynamics simulations (Zakrzewska and Lavery, 1999). Such simulations are currently too short to allow the complex formation process to be studied, but they can provide an ensemble of conformational "snapshots", which may then be analyzed using simple solvent models to estimate interaction-free energies. This method is applicable to studies of point mutations (within the binding protein or its DNA target), but is hindered when complex formation involves large structural rearrangements (Gohlke and Case, 2004). This problem is also a major hurdle for docking algorithms that are required to identify the interaction geometry if no experimental data is available or if mutations significantly perturb this geometry.

For complexes of known geometry, approaches related to the threading algorithms used in protein fold identification (*see* Article 72, **Threading for protein-fold recognition**, Volume 7 and Article 99, **Threading algorithms**, Volume 8) enable sequence-dependent binding and DNA deformation energies to be estimated very rapidly (Paillard and Lavery, 2004). Results for a range of DNA binding proteins confirm that indirect recognition often plays a major role and also show that the sequence selectivity of neighboring base pairs within the target sequence may be correlated, a problem ignored by conventional weight matrices (Benos *et al*., 2002). Such approaches are a promising route for extending data on known complexes to the study of other (closely) related proteins.

Whatever theoretical approaches are developed, it should not be forgotten that a major challenge will be to go beyond binary complexes and to understand the sequence-recognition processes involved in constructing multiprotein assemblies

such as the nucleosome or the transcriptosome (*see* Article 33, **Transcriptional promoters**, Volume 3).

3. Large DNA fragments

Despite the progress made in atomic scale simulations of DNA, applications to fragments containing more than 100 or so nucleotides are unlikely. Understanding the behavior of fragments many times this length therefore requires coarse-grained approaches (Orozco *et al*., 2003; Schlick, 2002). Elastic rod models are a natural answer to such problems. Such models exist at various levels of sophistication and may treat DNA as a uniform rod or may take into account anisotropy (e.g., easier bending towards the grooves of the double helix). The generic effects of base sequence (e.g., intrinsic or protein-induced curvature) have also been investigated, although, for the reasons discussed above, modeling the properties of arbitrary biological sequences is hindered by insufficient data. Recent results showing that very small DNA fragments (<100 bp) can cyclize with unusually high probabilities (Cloutier and Widom, 2004) also suggest that sharp, possibly sequence dependent, bending or "kinking" needs to be added to present rod models. Nevertheless, the generic studies have already shown that the local properties of DNA can have an impact on a mesoscopic scale, for example, by bringing together two distant sequence fragments as the result of an intrinsically bent segment placing itself at the highest radius of curvature within a supercoiled structure. It should also be noted that local curvature influences not only the pathway of the adjoining segments but also their rotational state and this can be important for the formation of contacts between distantly bound proteins.

Coarse grain models have many possible uses, but a biologically important application will be in probing the physical organization of genomes, whether this involves the relatively simple packing of naked DNA into a phage head (Purohit *et al*., 2003) or the organization of the nucleus within higher organisms (O'Brien *et al*., 2003). Note that large genomes can be represented by simplified bead models, akin to those used in polymer physics, where a single bead represents hundreds or thousands of base pairs. Ideally, progress in this field will allow smooth passages to be created from the most refined all-atom models to very coarse grain approaches with, in addition, the possibility of combining several levels of representation within a single study.

4. Future challenges

Beyond the standard wish list for specialists of molecular simulation (longer dynamic trajectories for larger molecular systems with more refined interaction potentials), DNA modeling should be able to help in translating a variety of experimental information into structural or dynamic data. This is already the case for the increasingly sophisticated refinement procedures used in crystallography or NMR spectroscopy, but other challenging areas include the calculation of chemical shifts, which would greatly extend the applicability of NMR data (Wishart and Case,

2001), and the simulation of circular dichroism or infrared spectra, which would allow a more quantitative use of these inexpensive experimental techniques. In this area, one can also cite the interpretation of the force curves resulting from mechanical experiments on single molecules or single molecular complexes (Lavery *et al*., 2002).

Quantum chemistry calculations of the electronic structure of DNA are still in their infancy, but are undoubtedly important for understanding interactions with radiation (UV, γ-rays), or chemical species such as drugs and mutagens. DNA conductivity (can DNA be used as an electric wire?) is another area where quantum chemistry needs to be coupled with molecular dynamics simulations to resolve experimental contradictions (Endres *et al*., 2004). The results of such calculations will be important for progress in the nanotechnological applications of DNA. Related studies of how electronic excitations move along DNA are also necessary for understanding DNA damage.

Lastly, more accurate and efficient methods of extracting thermodynamic data from molecular simulations would be important in analyzing not only DNA interactions with other molecules, but also in areas such as strand hybridization, in order to refine the interpretation of microarray data (*see* Article 57, **Low-level analysis of oligonucleotide expression arrays**, Volume 7) and to improve the selection of the DNA sequences already used in a wide variety of autoassembly processes (*see* Article 8, **Real-time DNA sequencing**, Volume 3). These goals imply an understanding of the properties of single-stranded DNA, which is currently as problematic as the treatment of unfolded polypeptide chains.

Short Specialist Review

Modeling tertiary structure of RNA

Benoît Masquida and Eric Westhof
Université Louis Pasteur, Strasbourg, France

1. The modeling process

The starting point for modeling an RNA molecule is the 2D or secondary structure that ideally represents, on a planar drawing, the Watson–Crick paired helical regions linked by non-Watson–Crick paired helical segments: hairpin loops, internal bulges, and multiple junctions (*see* Article 96, **RNA secondary structure prediction**, Volume 8 and Article 27, **Noncoding RNAs in mammals**, Volume 3). Secondary structure diagrams provide a framework-summarizing sequence and biochemical data without providing a full structural basis. The folded architecture results from the assembly of the helical framework through interactions between the helices and the single-stranded regions. The assembly often appears modular with a recognizable hierarchy and modules, recurring in various RNAs, and that assemble into a fold in a concerted fashion. There are three main categories of tertiary structure interactions: those between two double-stranded helices, those between a helix and a single strand, and those between two single-stranded regions. A modeling process based on this principle of natural folding processes has been developed (Westhof *et al*., 1996). Modules can be either architectural (forming a bend, e.g., kink-turn motif (Klein *et al*., 2001), or a reorientation within a helix or between helices) or anchors for association (e.g., tetraloop–tetraloop receptor interaction; Cate *et al*., 1996). Modules generally contain RNA motifs that we define as an ordered assembly of non-Watson–Crick base pairs (Leontis and Westhof, 2003).

Because of the underlying sequence variations within the motifs (the rules of which are still unknown), it is crucial to perform extensive sequence alignment and secondary structure analysis prior to any 3D (three-dimensional) modeling in order to identify with confidence the nature of the various motifs. The secondary structure can then be parsed into modules based on elementary motifs, the 3D coordinates of which can be generated later using appropriate programs (see below). Afterward, these modules can be assembled to form the RNA architecture. Finally, the geometry of the model is regularized using least-square refinement. In this process, hydrogen bonds between nucleotides are used as explicit constraints.

One of the most difficult tasks is the arrangement of the multiple-way junctions. Usually, a 2D structure is a set of hairpins linked together by various single-stranded

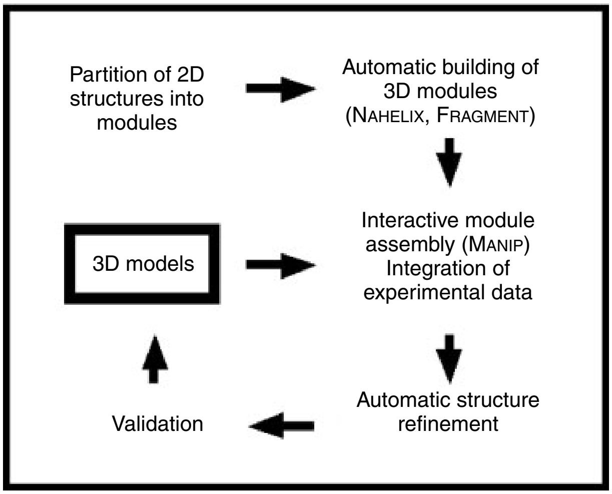

Figure 1 Diagram of the modeling process described (Massire and Westhof, 1998). From an accurate sequence alignment, the secondary (2D) structure can be deduced. Then, the first step consists of partitioning the 2D structure into modules for which 3D coordinates can be generated using adequate computer programs. These modules can then be assembled interactively on a graphic computer. When all the modules are placed next to each other while respecting the covalent linkages of the RNA chain, refinement can be performed. Validation of the model proceeds through collating it to biochemical data. Additional steps of interactive modeling refinement can be performed until the model is fully satisfactory

regions and junctions. The main problem is then the proper choice of helices that stack on each other. If an internal loop lies within a helical stem, does it favor coaxial stacking or does it make a kink that prevents coaxially stacking between the helical parts of the stem? In the case of 3-way or 4-way junctions, which helices do stack, if any? A thorough analysis of the sequence of the junctions should be performed to exhibit features homologous to junctions for which a crystal structure is known. If no convincing homology is found, assumptions should be made that eventually lead to the building of several models (Westhof *et al*., 1996). Then, tertiary interactions coupled to biochemical data may help to discriminate between the various possibilities.

The suite of in-house modeling programs runs on SGI graphical stations under the IRIX 6.2 system or beyond. Figure 1 summarizes the overall process. The MANIP (Massire and Westhof, 1998) package contains programs dedicated to generate 3D coordinates from the sequence information, and is available at the URL **http://www-ibmc.u-strasbg.fr/upr9002/westhof/**.

2. Getting the right secondary structure

In order to build a reasonable secondary structure for a given RNA, one needs to collect and align enough sequences to perform statistical analysis of the sequence variations. Chemical probing techniques can compensate for a lack of sequences

and help discriminate between various possibilities (Powers and Noller, 1991). With experience, secondary structure prediction programs such as MFOLD can be invaluable (Zuker, 2003; Ding and Lawrence, 2003). The latter approach is the only theoretical method that can be used when a single sequence is available. As a first step of the molecular modeling process, sequences are roughly aligned according to fully conserved nucleotide stretches, if present. Then, helices can be identified by checking for sequence covariations obeying Watson–Crick rules. Within this scenario, conserved Watson–Crick base pairs cannot be proven and, thus, should be regarded as nonproven or with extreme caution. Finally, the RNA parts that do not follow the Watson–Crick rules can be suspected to form specific tertiary motifs that should be analyzed for sequence homologies to motifs of known 3D structures.

3. Extrusion of the secondary structure in three dimensions

Two complementary programs help extruding secondary structure elements into three dimensions and have been described elsewhere (Westhof, 1993).

- NAHELIX is dedicated to building nucleic acid helices, and is run using either a graphical interface or interactive mode in a shell window. The program reads the sequence length, numbering, and sequence as input, and outputs a coordinate file for all the RNA atoms of the described sequence.
- FRAGMENT threads any sequence over a known 3D structure. A given structure file can be transformed to a fragment file that contains no sequence information, but only important conformational parameters for maintaining the sugar-phosphate backbone characteristic of the motif. Then, a polynucleotide backbone with any base sequence can be threaded onto that of the starting folded polynucleotide, which considerably facilitates the building of variants of a given motif.

4. Interactive molecular modeling

Once all secondary structure elements have been built in 3D, they can be assembled interactively using the MANIP program (Massire and Westhof, 1998). MANIP is a user-friendly program operated by pop-up menus in the main window. It allows definition of zones that can be independently moved using the `move` command in order to generate a 3D model. The other main modeling function is `tor`, which activates all the dihedral angles of a selected residue. A switch allows the user to quickly activate dihedral angles from previous or next residues all along the RNA chain. RNA fragments can thus be moved like tentacles and efficiently linked to each other.

5. Refinement of the model

Refinement of the model is achieved by geometrical least-squares using the Konnert–Hendrickson algorithm (Konnert and Hendrickson, 1980) implemented

in the program NUCLIN/NUCLSQ (Westhof *et al*., 1985). The algorithm takes into account bond lengths, valence angles, dihedrals, and has antibump restraints. The resulting function is minimized against a dictionary of values that have been observed in high-resolution crystal structures of nucleotides and oligonucleotides. Since the refinement program optimizes the geometry along the steepest descent, the conformation of the starting model should not contain extremely distorted regions to avoid refinement failure. The refined model can then be collated to the data, and the process of interactive modeling and least-square refinement can be iterated until the model is satisfactory. A subset of the data should be used as a blind test during the building of the model so as to help validating the model. Further steps of interactive modeling may then be required until a satisfactory solution is reached.

6. Conclusions

The availability of genome sequences (URL **http://www.tigr.org/**), comparative sequence analysis to elucidate RNA structure, both at the level of secondary and tertiary structures, has already undergone wide use (Lambert *et al*., 2004). Second, major improvement in modeling the tertiary structure of RNA results from the increasing number of available RNA crystal structures that provide a structural basis to understand sequence variations. Third, this surge in sequence and 3D data has led to the development of several computer tools for analysis and comparisons. Nowadays, sequences and crystal structures can, thus, be merged together in order to decipher the rules governing nucleotide interactions in complex RNA motifs, and, hence, provide new tools to unravel RNA structures (Gendron *et al*., 2001; Waugh *et al*., 2002; Yang *et al*., 2003). A powerful tool for building tertiary folds of RNA molecules has been developed by F. Major with the MC-Sym suite of programs (Major *et al*., 1991; Major and Griffey, 2001). In the end, modeling the tertiary structure of RNA molecules ab initio or by assembling homologous modules is still a process fraught with difficulties, especially in the absence of sufficient aligned sequences. Although a coarse-grained architecture can be derived for structured RNAs rather successfully, atomic details and contacts do not lead to reliable predictions for either RNA–ligand interactions or catalytic mechanisms.

Introductory Review

Introduction to ontologies in biomedicine: from powertools to assistants

Russ B. Altman
Stanford University Medical Centre, Stanford, CA, USA

Ontologies are a "specification of a conceptualization" (Gruber, 1993). They provide a structured way to discuss an area of knowledge by specifying a controlled set of terms with well-defined meanings. They also provide (and this distinguishes them from a simple glossary or dictionary) a formal set of constraints on the relations between terms, so that the ontology can only be used to make statements that are semantically valid. We define terminology, ontology, qualitative represesentations, and quantitative representations in more detail below, and explore these even more deeply within this section of the encyclopedia. The first key point about ontologies, however, is that they allow us to build computational representations of knowledge, to go along with the standard computational representations of data.

What is the difference between data and knowledge? This question touches many deep philosophical issues, but for the purposes of this discussion, we can define data as pieces of information, usually of basic "types" (strings, integers, real numbers, Booleans), and often organized in a table, such as a spreadsheet. Thus, for biology, data may include genome sequences, expression levels, protein levels, protein locations, and measurements of physical interactions between molecules. Knowledge is the principles or rules that are generated by an analysis of data that allows different "columns" of a spreadsheet to be related by rules or equations. There are many ways to express the relationships between data elements, and these include relational calculus, statistical associations, axiomatic rule systems, first-order logic, natural language, and other formal and informal systems. In biology, knowledge may include the rules for turning gene expression on and off, the rules for folding protein molecules, the rules for trafficking proteins to their appropriate cellular location, and the networks of regulatory or metabolic interactions that produce the emergent phenomena associated with cellular life.

The field of Artificial Intelligence emerged in the 1970s and 1980s with the goal of producing high levels of performance in tasks normally associated with the need for human intelligence. A variety of technologies emerged, and one of them was expert systems. One of the ideas behind expert systems such as Dendral (Lindsay *et al*., 1980), Mycin (Buchanan and Shortliffe, 1984), and Molgen (Feigenbaum

and Martin, 1977) was that complex performance could be achieved by organizing expert knowledge (in this case, as a set of rules that could be chained together) and then by applying relatively simple algorithms to the organized knowledge to make inferences. The relative success of these systems led to adoption of the mantra that "Knowledge is Power" and the belief that time was best spent eliciting and organizing complex knowledge, and then writing relatively straightforward algorithms to use this knowledge. In the case of rules, forward and backward chaining algorithms were used to "prove" conclusions on the basis of evidence.

Bioinformatics has blossomed as a field because of the recent development of high-throughput biological data collection methods. These methods include genome sequencing, micorarray expression analysis (DeRisi *et al*., 1997), proteomics (Lowe and Jermutus, 2004; Zhu *et al*., 2003), and technologies for measuring metabolite concentrations (Watkins and German, 2002; Mendes, 2002). It is not surprising that the first generation of bioinformatics tools were simply concerned with managing this deluge of data. The data structures were simple, and the tasks were to collect the information, organize it, create databases to hold it, and to search through the collections using various similarity measures. Thus, for DNA sequences, the formats for exchange and storage (Genbank (Benson *et al*., 2004)) were created, basic tools for comparing sequences (Smith and Waterman, 1981; Needleman and Wunsch, 1970) and retrieving them (FASTA (Pearson, 1994), BLAST (Altschul *et al*., 1990)), and for characterizing alignments (Hidden Markov Models (Krogh *et al*., 1994), and many others) were created. Parallel activities have accompanied the emergence of other high-throughput data sources. These tools can often be characterized as "power tools" because they allowed biologists to manage the new wealth of information by either extending previous capabilities that were inefficient or providing new capabilities for systematically examining the data sets, and pulling out individual data items of interest.

The genomic ethic of high-throughput data collection and analysis has led to the emergence of a new approach to biology that has been called "systems biology" or "integrative biology". The key features of this approach are (1) emphasis on high-throughput data gathering, (2) focus on biological systems as a whole, and less as the sum of reduced parts, and (3) reliance on computation to facilitate progress. As part of this evolution, computers are being asked to perform increasingly complex tasks, including some previously performed only by human experts. These include mining and summary of the published literature, creation of pathways and networks based on the experimental associations between genes or gene products, integration of multiple disparate data sources, and comparison of entire systems (genomes, transcriptomes, proteomes), with the goal of generating hypotheses or even suggesting the next set of experiments. These activities have a distinctly different flavor from the powertools of bioinformatics, and really represent the need for intelligent computational assistants to help biologists in their work. One example of an assistant might be a computer program that looks at clusters of genes (generated by a microarray expression clustering powertool) and determines the degree to which the literature on these genes supports their association in a cluster (Raychaudhuri *et al*., 2003; Raychaudhuri and Altman, 2003; Raychaudhuri *et al*., 2002).

The computational infrastructure required to support a biomedical research enterprise that integrates automatic assistants into the process of science is quite

substantial. In particular, there are four main capabilities that are required, and all of these can be considered "knowledge structures" upon which the assistant algorithms of the future will work. These are:

1. *Terminologies.* The first step in creating a durable knowledge infrastructure is to have a standard set of terms, with agreed-upon meanings for each of the domains of biology. These terminologies must be constantly maintained and updated as knowledge expands, but must retain backward compatibility as much as possible, in order to allow programs upon which they are based to continue functioning. Examples of current terminologies that serve as a useful starting point for the biomedical knowledge infrastructure are the MESH terminology used by the National Library of Medicine (NLM) to index Medline/PubMED articles, the UMLS from the NLM that integrates a number of biomedical vocabularies into a common framework (Bodenreider, 2004), the Human Genome Nomenclature Committee (HGNC) gene-naming conventions (Povey *et al*., 2001), elements of the Gene Ontology for classifying gene function (Ashburner *et al*., 2000), and many others.
2. *Ontologies.* The next step in creating the biomedical knowledge infrastructure is the expression of the allowed semantic relationships between terms in the terminologies. For example, in addition to having a term for "Amino acids", "proteins", "genes", and "translation", we need to be able to state that "amino acids" are part of "proteins" and that "genes" are translated into "proteins". This challenge includes at least two parts: the definition of languages for expressing relations and then the acquisition and coding of the actual relations that are relevant in biomedicine. Just as for terminologies, the need to maintain ontologies as a dynamic structure is critical. Ontologies allow us to encode the semantics of our understanding of biological relationships and, therefore, biological knowledge.
3. *Qualitative representations of biological processes.* Terminologies provide us with the basic entities. Ontologies provide the language for expressing relationships between these entities. We use these tools, then, to create complex computational descriptions of our current understanding of biological models. Thus, we may use an ontology to create a qualitative description of the processes, of transcription, translation, protein trafficking, degradation, or other biological processes. These models will necessarily be incomplete, but at any given time they will capture the current best understanding of how things work. Most biological theories begin as qualitative relationships, and only achieve quantitative precision through the execution of experiments designed to characterize the detailed physical and temporal features of these theories. Thus, a qualitative level of representation provides the freedom to experiment with prototype ideas that are not yet quantitatively expressed. Work in this area has included the use of Petri Nets for modeling biological systems (Peleg *et al*., 2002), and the creation of probabilistic models based on statistical associations found in high-throughput data sets (Friedman, 2004; Segal *et al*., 2003; Stuart *et al*., 2003).
4. *Quantitative representations of biological processes.* Eventually, there is sufficient information in a model of a biological process to allow the creation of a quantitative mathematical model that can be used to perform precise simulations of the modeled domain of biology. The resulting quantities, concentrations, and

interactions can be independently validated by comparison with experiments, and the resulting inconsistencies can feed back on the terminologies, ontologies, and qualitative models upon which the simulation was based. In many ways, a faithful mathematical representation of biological systems is an ultimate goal of bioinformatics and computational biology. There have been precious few examples of successful simulations (and always in systems of limited scope, including the lambda-phage lysis or lysogeny decision (McAdams and Shapiro, 1995) or intracellular calcium flux (Slepchenko *et al*., 2002)), but these are the ultimate indication of our understanding of a biological system.

As biological theories become more complex, and the data supporting them becomes more voluminous, computational storage of the theories and the data will be mandatory. Unfortunately, although data can be scored fairly efficiently using current storage technology, the available technology for representing and storing knowledge is still immature. There is still resistance to the idea that computers can be "trusted" with knowledge, and some believe that manipulating knowledge is still strictly the domain of the human mind. Although the current supremacy of the human intellect at managing complex ideas and theories cannot be denied, the value in capturing some or all of this capability in digital computers seems clear. The ability of computers to systematically generate and test hypothesis and mine large volumes of data for associations suggests that they will be able to assist humans in the scientific enterprise when they can represent human knowledge in an effective manner.

This section of the encyclopedia is devoted to the discussion of the second element of the biomedical knowledge infrastructure: ontologies. There is active and important work on all the elements, some of which is reviewed in other parts of this volume. The work on ontologies is particularly important because it promises to provide the basis for the qualitative models of the future, which in turn will evolve into mathematical representations. The elements of this section include first a brief review of the key terminologies in the UMLS (UMLS and associated vocabularies), reviews of the different ontology conventions and representation languages that have been proposed (Frame-based systems, Description Logics, The Gene Ontology Project), basic technologies for managing ontologies (Automatic Concept Identification, Merging and Comparing Ontologies), important general applications of ontology technology (Ontologies for data integration, Ontologies for information retrieval, Ontologies for natural language processing, and a review of TAMBIS), and finally, important emerging application areas in which ontology design and adoption is a major limiting factor for progress (Representing and reasoning about pathways, Ontologies for 3D molecular structure, Ontologies for Proteomics). This is a dynamic and exciting time for the applied science of building and using ontologies, because biomedicine has a clear and present need for these technologies, which are needed to build the next generation of application algorithms.

Introductory Review

BioPAX – biological pathway data exchange format

Gary D. Bader, Michael P. Cary and Chris Sander
Memorial Sloan-Kettering Cancer Center, New York, NY, US

1. Introduction

To understand biological processes, we must integrate new observations with existing knowledge to create testable models that can be iteratively refined. This will be successful only if the vast amounts of data gathered by large-scale profiling of biological features, such as mRNA transcripts and proteins, can be efficiently integrated with data from literature and databases for visualization and analysis. Collecting and integrating biological pathway data is vital for this process. As the number of pathway databases increases, pathway data integration becomes more difficult. At the start of 2006, there were over 215 databases containing pathway information, widely varying in form and content (**www.pathguide.org**). A standard exchange format – a common language – for pathway data, supported by major pathway databases, will significantly reduce the amount of time and energy spent by computational biologists on data integration and lead to increased use of pathway data for biological process modeling, visualization, and analysis (Cary *et al*., 2005).

2. What is a pathway?

One abstraction that biologists have found extremely useful in their efforts to describe and understand the inner workings of the cell is the notion of a biomolecular network, often called a *pathway*. A pathway is a set of interactions, or functional relationships, between the physical and/or genetic (Tong *et al*., 2004) components of the cell which operate in concert to carry out a biological process. Despite tremendous variety in the cellular processes described as pathways, several pathway representation patterns are prevalent in current practice: metabolic, signaling, gene regulation or genetic. These distinctions are mainly organizational, since the cell map represents a fully connected molecular network. Metabolic pathways are generally composed of a series of biochemical reactions geared toward metabolite conversions, whereas signaling pathways generally involve protein–protein interactions and posttranslational modifications. Gene regulation

networks capture transcription factors and the genes they regulate. Genetic pathways are composed of genetic interactions, such as epistasis or synthetic lethality, which occur when two mutations have a combined phenotypic effect not caused by either mutation alone. Additionally, proteomics and functional genomics studies detect molecular interactions, such as protein–protein and protein–DNA, without much detail, but with unparalleled and unbiased coverage (Bader *et al*., 2003).

3. BioPAX – a common language for pathways

BioPAX (**www.biopax.org**) is a community-based effort to develop a biological pathway data exchange format. All development is performed by the BioPAX Workgroup, composed of interested members of pathway database groups and the user community. BioPAX Level 1, which focuses on metabolic pathway information, was released in July 2004. BioPAX Level 2, which adds support for molecular interactions via inclusion of the Proteomics Standards Initiative-Molecular Interaction (PSI-MI) data model (Hermjakob *et al*., 2004), was released in late 2005. Level 3, currently underdevelopment, will add improved support for signal transduction, which often requires the ability to define molecular states, and genetic regulatory networks. Future levels will be able to represent genetic interactions and generic molecules and processes.

BioPAX is being developed in a practical, leveled approach in which each level supports a greater variety of pathway data. BioPAX is implemented in Web Ontology Language (OWL), a standard Extensible Markup Language XML-based language designed for representing ontologies, composed of such things as class hierarchies, properties, and controlled vocabularies. The BioPAX format and any associated software developed by the BioPAX workgroup are open source and freely available to all under the GNU LGPL license (**www.gnu.org/copyleft/lesser.html**). The BioPAX group is coordinating work with other pathway related standards initiatives, such as Systems Biology Markup Language (SBML) (Hucka *et al*., 2003), CellML (Lloyd *et al*., 2004), and PSI-MI (Hermjakob *et al*., 2004), to minimize duplication of work and to ensure compatibility with these standards in areas of overlapping coverage.

4. The BioPAX ontology

Pathways, interactions, and physical entities form the basis of the BioPAX ontology. Four basic classes are defined: the root level entity class and its three subclasses: pathway, interaction, and physicalEntity. *Entity* is a discrete biological unit used when describing pathways and contains a number of basic properties, such as name, database links, and data source, inherited by all subclasses (most of the classes in BioPAX). *Pathway* is a set of interactions or pathway steps with associated evidence. *Interaction* is a relationship between two or more entity participants. *PhysicalEntity* is a tangible physical object, such as a molecule. Physical entities are frequent building blocks of interactions. Interactions at this level are very

general, as they can occur between pathways, interactions, or physical entities. For instance, protein–protein, small molecule–pathway, and pathway–pathway interactions are all valid at this abstract level of the class hierarchy. This allows BioPAX to be flexible when confronted with new types of pathway information. Specialized versions of the interaction class are defined by creating subclasses, which limit the types of entities that can interact and further define properties specific to each interaction type. In this way, classes become less abstract as the hierarchy is traversed from class to subclass, though the number of levels and classes is limited. In this way, the BioPAX ontology remains expressive enough to capture important levels of abstraction that exist in biology, while remaining simple and accessible.

BioPAX Level 2 defines seven main types of interaction and four types of physical entity. Interactions types are: conversion (and three subtypes: complex assembly, transport, biochemical reaction) and control (and two subtypes: catalysis and modulation); physical entities type are: complex, protein, RNA, DNA, and small molecule.

Pathway information in BioPAX is represented by creating instances of these classes. For example, defining a typical enzyme-catalyze biochemical reaction requires physical entity instances for the substrates, products, and enzyme, a biochemical reaction instance to describe the conversion of the substrates to the products, and a catalysis instance to define the relationship between the enzyme and the reaction. For more detail, see the full documentation at **www.biopax.org**.

5. How can BioPAX be used?

5.1. Pathway data warehouse

A pathway data warehouse collects all available pathway information in one place so that it can be conveniently accessed. BioPAX could make creation of pathway data warehouses easier if many databases provided access to their data in the BioPAX format as only the BioPAX format would have to be converted instead of converting a different format for each available dataset.

5.2. Molecular profiling analysis in a pathway context

Molecular profiling experiments, using such technologies as gene expression microarrays and mass spectrometers, are often compared across two or more conditions (e.g., normal tissue and cancerous tissue). The result of this comparison is often a large list of genes that are differentially present in the tissue of interest. It is interesting and useful to analyze these lists of genes in the context of pathways. For instance, one could look for pathways that are statistically overrepresented in the list of differentially expressed genes. The result is a list of pathways that are active or inactive in the condition of interest compared to a control. The list of pathways is often much shorter than the list of differentially expressed genes and thus easier to comprehend.

BioPAX could facilitate this and other kinds of pathway-based analyzes by giving analysis tools easy access to a large body of pathway data in a common format.

5.3. Visualizing pathway diagrams

Pathway diagrams are useful for examining pathway data, as they provide an efficient way to present large amounts of data via the human eye. A number of formats are available for pathway images, but only a few available viewing tools link components such as proteins in the image, to underlying data. A mapping of BioPAX to a symbol library for pathway diagrams (such as Kohn maps (Kohn, 1999) could be used as a basis for a general pathway diagram generation tool.

5.4. Pathway modeling

Mathematical modeling to describe and capture the dynamics of a pathway system is a frequent use of pathway information. Many of the tools available for pathway modeling support the SBML (**sbml.org**) and CellML (**www.cellml.org**) standards, which describe models in sufficient mathematical detail to allow model sharing between tools (actual mathematical equations describing the rates of component reactions in the pathway are captured). While BioPAX is not designed to represent pathway models in high mathematical detail like SBML and CellML, it contains a number of biological concepts not present in these standards, such as "protein" that are required for linking different data sets in a meaningful way. Use of BioPAX to annotate SBML and CellML models could allow linking models to pathway databases and their functional annotations.

6. Available data and tools

Major pathway databases and a growing number of tools support BioPAX. Three large academic metabolic focused pathway databases support BioPAX. The pathway and reaction subset of a significant number of the BioCyc collection of pathway genome databases, some carefully curated such as EcoCyc (Karp *et al*., 2002b), MetaCyc (Karp *et al*., 2002a) and some automatically reconstructed by computer with some curation, such as HumanCyc (Romero *et al*., 2005), are available in BioPAX Level 1 format at **www.biocyc.org.** The pathway database of the Kyoto Encyclopedia of Genes and Genomes (KEGG) (Kanehisa *et al*., 2004) is also available in BioPAX Level 1 format from the KEGG FTP site. The WIT database (Overbeek *et al*., 2000), makes all reconstructions of metabolic networks derived from public DNA sequence data available in BioPAX Level 1 format. Major academic signal transduction pathway focused databases are starting to make their data available in BioPAX Level 2. This includes the Reactome database (Joshi-Tope *et al*., 2005) of human-focused pathways, including metabolic and signaling pathways, the aMAZE (Lemer *et al*., 2004) pathway

database and the Integrating Network Objects with Hierarchies (INOH) pathway database (Fukuda and Takagi, 2001), all of which contain hand collected pathway information.

BioPAX formatted data can be visualized by the VisANT (Hu *et al*., 2004) and Cytoscape (Shannon *et al*., 2003) network analysis and visualization tools. Pathways in the PATIKA pathway visualizer and editor can be exported in BioPAX format. Since BioPAX is written in OWL, a number of generic OWL tools are available for storing, querying, browsing, creating, and editing BioPAX data. Protégé is a powerful ontology editor that is freely available and has been used with the Protégé OWL plug-in (Knublauch *et al*., 2004) to create the BioPAX ontology. SWOOP (Kalyanpur *et al*., 2004) is an OWL file browser that can be used with BioPAX pathways. Further a number of software libraries, such as Jena and OWL-API (Applications Programming Interface), written in Java, are useful for developing software that can read, process, and write BioPAX OWL files. OWL/RDF (Resource Description Framework) database storage tools, such as the Oracle RDF database and InstanceStore (Horrocks *et al*., 2004) are also available. Simple Protocol and RDF Query Language (SPARQL) and RDF Data Query Language (RDQL) languages act like Structured Query Language (SQL) for OWL/RDF data. More advanced querying tools, such as the Pellet reasoner, can take advantage of logic and the structure of an OWL ontology to allow more powerful queries. These generic OWL technologies are still new, so expect them to require maturation before they fulfill their promise of easy storage and manipulation of large amounts of BioPAX data. Finally, since OWL is XML based, any generic XML software development tools are compatible with BioPAX files.

7. Conclusion

The ultimate aim of projects like BioPAX is to enable effortless collection of pathway data so that it may be efficiently applied to answer biological questions. Ideally, biologists should never need to perform time-consuming data collection tasks in order to perform a particular analysis. Instead, they should be able to locate, retrieve, and apply data of interest without worrying about data models, exchange formats, or integration methods.

To achieve this goal, data standards must become broadly adopted by pathway databases. This would enable a variety of large-scale data integration approaches, such as a centralized or distributed pathway data warehouse or a query engine able to retrieve data from multiple standards-compliant primary databases. Importantly, pathway data analysis tools must be built to interface with these integration systems to make pathway data retrieval painless.

With public data sharing infrastructure, we can build software platforms that allow high-level and effective pathway data manipulation and analysis. When combined with the trend toward cheap, high-throughput cellular profiling technology, we can imagine a swift convergence on biological process understanding through iterative systems biology modeling methods.

Acknowledgments

BioPAX is a community effort and work has involved the following people: Level 1: Gary D. Bader, Erik Brauner, Michael P. Cary, Robert Goldberg, Chris Hogue, Peter Karp, Joanne Luciano, Debbie Marks, Natalia Maltsev, Eric Neumann, Suzanne Paley, John Pick, Aviv Regev, Andrey Rzhetsky, Chris Sander, Vincent Schachter, Imran Shah, Jeremy Zucker.

Level 2: Mirit Aladjem, Gary D. Bader, Michael P. Cary, Kam Dahlquist, Emek Demir, Peter D'Eustachio, Ken Fukuda, Frank Gibbons, Marc Gillespie, Chris Hogue, Michael Hucka, Geeta Joshi-Tope, David Kane, Peter Karp, Christian Lemer, Joanne Luciano, Natalia Maltsev, Eric Neumann, Suzanne Paley, Elgar Pichler, Jonathan Rees, Alan Ruttenberg, Andrey Rzhetsky, Chris Sander, Vincent Schachter, Andrea Splendiani, Mustafa Syed, Edgar Wingender, Guanming Wu, Jeremy Zucker.

The BioPAX workgroup has been coordinated by Mike Cary and Gary Bader in Chris Sander's group with help from many of the above mentioned people.

Specialist Review

Ontologies for the life sciences

Steffen Schulze-Kremer

Barry Smith
Universität Leipzig, Leipzig, Germany
University at Buffalo, Buffalo, NY, USA

1. Introduction

The multitude of heterogeneous and autonomous data resources available to life scientists today includes genomic (Fasman *et al*., 1996), cellular (Jacobson and Anagnostopoulos, 1996), structural (beginning with the seminal Bernstein *et al*., 1977), phenotype (McKusick, 1994), and a range of other types of biologically relevant information (Bairoch, 1993). Even for one type of information, for example, DNA sequence data, there exist several databases of different scope and organization (Fasman *et al*., 1996; Keen *et al*., 1996; Benson *et al*., 1997 and their successors).

There exist terminological differences (alternative synonyms, aliases), syntactic differences (in file structure, separators, spelling), and semantic differences (the same words are used to mean different things in different sources). Conventions for naming data objects, object identifier codes, and record labels differ between databases and do not follow a unified scheme. Even terms for important high-level concepts and relations that are fundamental to life sciences are often used in conflicting or ambiguous ways (Smith and Rosse, 2004).

One prominent example is the concept *gene*. For GDB (Fasman *et al*., 1996), a gene is a "DNA fragment that can be transcribed and translated into a protein". For GenBank (Benson *et al*., 1997) and GSDB (Keen *et al*., 1996), a gene is a "DNA region of biological interest with a name and that carries a genetic trait or phenotype". The latter definition is problematic, not only because it makes the answer to the question of which genes exist depend on the vagaries of human naming acts but also because it comprehends nonstructural coding DNA regions such as intron, promoter, and enhancer. There is a clear distinction between the two underlying notions of *gene,* but both continue to be used, thereby adding another level of complexity to data integration. Another term with multiple meanings is *protein function* (biochemical function, e.g., enzyme catalysis; genetic function, e.g., transcription repressor; cellular function, e.g., scaffold; physiological function, e.g., signal transducer).

If a user queries a database using an ambiguous term, she must herself take responsibility for verifying the congruence in meaning between her use of the term and what the database returns. Those semantic incompatibilities that are known must be resolved with each new search result, while those that are unknown propagate errors behind the scenes. Ontologies can help resolve such incompatibilities in a global fashion, for example, by flagging cases where a single term is used for entities in distinct ontological categories and enforcing manual disambiguation.

The advent of microarray technology for mRNA expression analysis requires additional standardization in terminology for characterizing not only genes, tissues, and samples but also experimental setups and the factors involved in mathematical postprocessing of raw measurements. A comparison between different experiments is only feasible if consistent terminology and standardized input forms are used. The development of ontologies suitable for this purpose is pursued by the MGED consortium (Brazma *et al*., 2001).

Standardized nomenclatures are required also where the new more integrated approach to biology has led to the merging of subfields with historically independent origins. This applies, for example, to genetics, protein chemistry, and pharmacology. Pharmaceutical companies have expressed an urgent need to harmonize the technical languages of these fields so that the knowledge derived from each can be stored in a unified way. The fast growth of sequence, structure, expression, metabolic, and regulatory data pertaining to many organisms adds additional pressure to utilize standardized and compatible nomenclature in molecular biology.

Text mining and natural language understanding in biology can also profit from ontologies. Currently, it is mostly techniques based on string-based statistical and proximity approaches that are applied to text analysis. Ontologies can, however, support parsing and disambiguating sentences by enforcing grammatically compatible uses of terms via rules for ontologically compatible combinations of referents (Jackson and Ceusters, 2002; Nirenburg and Raskin, 2001).

To support consistent reporting of results in molecular biology, it will be necessary to develop controlled vocabularies comprehending the most important and frequently used terms with coherent definitions in such a way as to allow database managers, curators, and annotators to create new and more coherent software and database schemata, to provide exact, semantically precise specification of the concepts used in existing schemata, and to curate and annotate existing database entries in a consistent way.

It is important to understand that terminological ambiguity affects not only interoperability on the level of computers but also communication between human beings. But where humans have the facility to resolve ambiguities in an efficient way, computer programs and databases have, for the moment at least, no analogs of the capabilities that allow such concurrent disambiguation. Ontologies are one important tool designed to make up for this shortfall.

Data integration, too, must overcome the problem of syntactic and semantic heterogeneity. While some syntactic incompatibilities, for example, prefix versus postfix operators, can be easily aligned automatically, incompatibilities that arise from differences in meaning require manual resolution within a common unifying framework. Thus, for example, each table, object, and so on, of one database must be manually aligned with the corresponding components of each other database that

is to be integrated. If we begin with *n* databases, and if the process of integration is carried out in pairwise fashion, then this requires $n*n$ attempts at resolution of differences in meaning. If, however, a single ontology exists that can serve as a central switchboard for those *n* databases, then the integration effort is reduced from $n*n$ to *n*, since each database has to be mapped to the ontology only once in order to become interoperable with any other database (Köhler and Schulze-Kremer, 2002).

2. Overview of ontologies

Work in ontology can be classified along a number of distinct dimensions. Most important is the distinction between (1) ontology as the study of beings or entities, the study of what exists at the highest level of abstraction – ontology as a branch of philosophy – and (2) domain ontologies, which result from the analysis of particular domains of reality and correspond broadly to separate areas of scientific inquiry.

Ontologies in either of these senses are, in principle, language independent. Thus, there can be a German equivalent to an English domain ontology, even if the actual translation process need not be trivial. A domain ontology may also be formalizable in some artificial language such as the language of first-order predicate logic, Description Logic (Rector *et al*., 2003), or some other form of representation formalism.

Ontology as a branch of philosophy can be important in bringing clarity to the life science field even before we enter the specific territory of biological domain ontologies. Thus, consider the fact that "DNA" can be used to designate quite different entities. First, there is DNA as physical stuff, which can be measured with a spectrophotometer. Second, there is the class of all of the chemical substances that share the general features common to DNA molecules. Third, there is the family of specific types of sequences or strings in the sense of abstract structures that can be subject to mathematical operations but cannot be measured or detected in reality. Fourth, "DNA" is often used in the lab to refer to a particular instance of a sequence, for example, the DNA sequence of *E. coli* K12 that can be stored in a database and needs carrier (memory chip, paper) to survive. These and similar distinctions – between classes and instances, between sequences and stuffs – are distinctions between philosophical categories, which have analogs in a number of different domains, and which are unfortunately often the source of confusions, not least when attempts are made at systematic representation of empirical knowledge for purposes of automatic information retrieval.

Among domain ontologies, we can draw distinctions between ontologies of varying scope and content. Thus, we can distinguish between

- upper-level ontologies, which are primarily concerned with the small number of general categories (such as *cell*, or *gene*, or *molecule*) that serve as the basis of our understanding of a particular domain;
- terminology-based ontologies, which are centered around the many highly specific terms used in the formulation of the results of scientific inquiry (such as *enzyme active site formation, postsynaptic membrane,* or *receptor signaling protein activity*).

Since the world around us in general and molecular biology and bioinformatics in particular are such as to manifest an enormous multidimensional complexity, no single ontology can suffice for every purpose. Rather, we must content ourselves with ontologies representing different views of reality created in connection with practical goals – often views of reality at different levels of granularity (Bittner and Smith, 2003). Thus, before building an ontology, it is important to understand what is its intended use, since otherwise there is a risk of being overwhelmed by the multitude of facets by which we are confronted. This aspect is acknowledged by the use of the term “situated ontologies” (Mahesh and Nirenburg, 1995) to emphasize the fact that a domain ontology should be evaluated with respect to its intended use.

The larger terminology-based ontologies clearly must be constantly updated in light of new experimental evidence and developments in language usage. At the highest levels, however, an ontology is designed to be much more stable than, for example, a database schema. The latter is dependent on specific choices concerning a database representation formalism, database management system, and requirements from the applications that access the data. Since an upper-level ontology is by its nature designed to be easily translatable from one knowledge representation formalism to another (given equivalent expressive capability), it can also be converted into a database schema. But a domain ontology addressing the fundamental categories and relations of an application domain is designed to be independent of given software implementations. When new knowledge classes are discovered, the ontology should be extendible in relatively straightforward ways, along lines to be described below.

The interplay between ontologies, biology, computer science, linguistics, and philosophy is depicted in Figure 1.

2.1. *Upper-level ontologies*

The first important ontologist was Aristotle (384–322 BC) who, among many other things, pursued the question of how reality is organized into classes or universals. His solution is presented in his *Categories*, which can be seen as the first upper-level ontology (Barnes, 1984). From Aristotle’s point of view, 10 categories suffice to express anything that can be known about something:

- Substance
- Quantity
- Quality
- Relation
- Place
- Time
- Situation
- Condition
- Action
- Affection.

Of course, from the point of view of the annotation of entities in molecular biology, the categories here distinguished will not suffice. However, if one subscribes

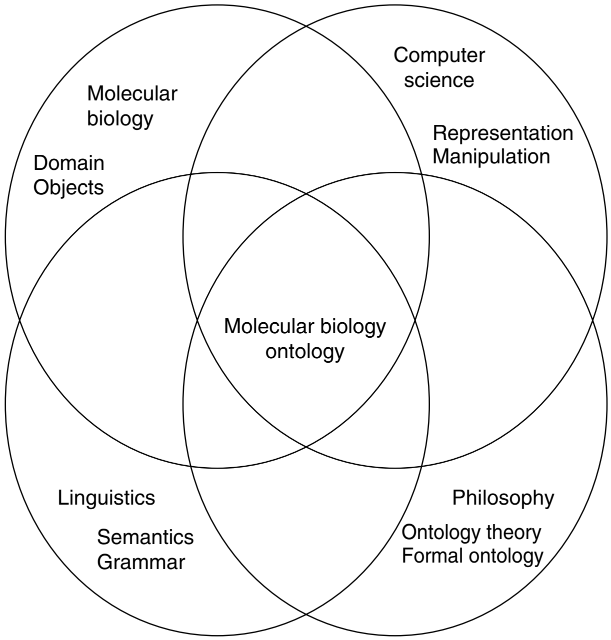

Figure 1 Molecular biologists discover facts that need to be organized and stored in databases. Computer scientists provide techniques for data representation and manipulation. Linguists help organize the meanings underlying database labels. Philosophers provide formal theories of basic ontological relations and principles governing the best practice in definition and classification

to the view that Aristotle provides a still serviceable account of the most fundamental set of categories, then one could see molecular biology and other special life sciences as the results of further subclassifications of Aristotle's categories into ever more specific kinds.

Another feature of Aristotle's ontology is the paucity of interconnections between his 10 categories, each of which is assumed to be an atomic category in the sense that it cannot be meaningfully decomposed into smaller units. Aristotle does allow that substance is the primary category, so that instances of all other categories are *dependent on* instances of substance. As concerns the interrelations between the nine "accidental" categories, however, he tells us too little. Later ontologists added further interrelations between their basic categories, including a taxonomy of different kinds of dependence relations provided by Husserl in his *Logical Investigations* (Husserl, 1970) and the related taxonomy offered in our own day by the DOLCE ontology and depicted in Figure 2 (Guarino, 1997; Masolo *et al*., 2003).

A contemporary philosophically motivated upper-level ontology for Molecular Biology (MBO) is advanced in Schulze-Kremer (1997). Like DOLCE, this starts from a single node, and it also extends to incorporate those physical and abstract entities that are relevant for biology and bioinformatics.

The upper level of the Molecular Biology Ontology (MBO) is shown in Figure 3. Starting from the root node *Being,* which includes all entities of any sort, it distinguishes two disjoint classes of *Object* and *Event,* which are discriminated on

- Entity
  - Particular (e.g., "large molecule", "green spot")
    - Concrete particular
      - Location
      - Object
    - Abstract particular
      - Set
      - Structure
  - Universal (e.g., "largeness", "color")
    - Property
      - Property kinds...
    - Relation

Figure 2 DOLCE top-level ontology

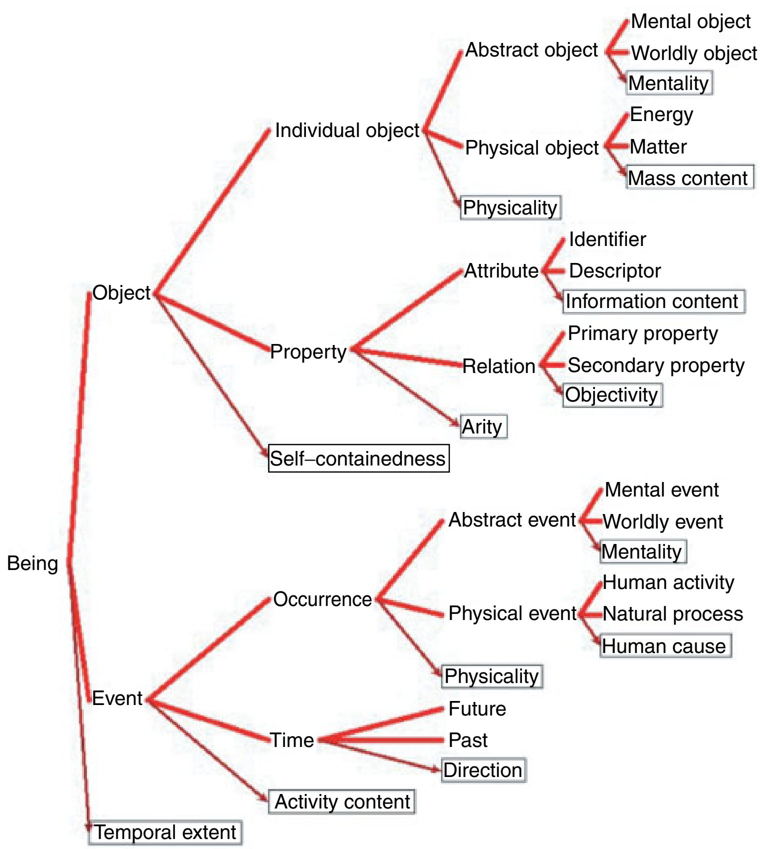

Figure 3 Upper level of the Molecular Biology Ontology of Schulze-Kremer (1997). Links represent the SUBCLASS-OF relation. Discriminating criteria are marked by arrows and boxes; thick lines denote disjoint subclasses (Reproduced by permission of The American Association for Artificial Intelligence)

the basis of their mode of existence in time. An *Object* retains its identity from one moment to the next; an *Event,* in contrast, is divided into temporal parts or phases and unfolds itself through these phases in successive moments of time. This distinction is passed on to all subclasses of *Object* and *Event*. The class *Object* is further subclassified into *Individual Object* and *Property*. Both preserve their identity from one moment to the next. They are discriminated on the basis of their ability to exist in a self-contained way. An *Individual Object* can stand alone, whereas a *Property* always needs another *Object* or *Event* of which it is the property. *Property* is further subclassified on the basis of distinctions in arity, into *Attribute*, a property with only one argument, and *Relation*, a property relating two or more *Beings*.

Attribute is subclassified into *Identifier* (e.g., "ID-2394873") and *Descriptor* (e.g., "*E. coli* R12 DNA") on the basis of whether an item simply labels an entity or carries additional information about it. *Relation* can be subclassified into *Secondary Property,* each instance of which involves some relation to a cognitive subject, and *Primary Property*, whose instances are objective and measurable entities such as mass or charge (Locke, 1975).

Individual Object is subclassified via the criterion of physicality into *Abstract Object*, which has no physical equivalent per se (except the capacity for being represented in writing, etc.), and *Physical Object*, which must have a defined spatial extent and/or energy content. *Physical Object* is further subclassified on the basis of mass content into *Energy* and *Matter*.

Abstract Object is further subclassified via the criterion of mentality – that is, according to whether it refers to an object within the mind or to an object in the outside world – into *Mental Object* (e.g., thought, love) and *Worldly Object* (e.g., circle, sequence).

The category *Event* is subclassified via the criterion of activity into *Occurrence*, in the instances of which at least one object participates, and *Time*, where this is not the case.

Time is further subclassified according to direction into *Past* and *Future*. Because the present moment is, strictly speaking, instantaneous, it does not appear in this branch. Analogous to abstract and physical objects, *Occurrence* is subclassified via the criterion of physicality into *Abstract Event* and *Physical Event.* The former is further classified on the basis of the criterion of mentality into *Mental Event* (e.g., thinking, feeling) and *Worldly Event* (e.g., binding, transport). *Physical Event* is subclassified on the basis of whether it is initiated by human intention into *Human Activity* and *Natural Process*. The operations of man-made devices in laboratory experimentation fall under the first of these two headings, the natural processes subject to molecular biological analysis under the second.

Another closely related more general purpose ontology is the Basic Formal Ontology (BFO) (Grenon *et al*., 2003; Grenon and Smith, 2004), which draws a still more radical distinction than that between *Objects* and *Events* by distinguishing two separate ontologies, called SNAP, for enduring entities (such as organisms, cells, enduring attributes, functions, and dispositions) and SPAN, for processes or events (Figure 4).

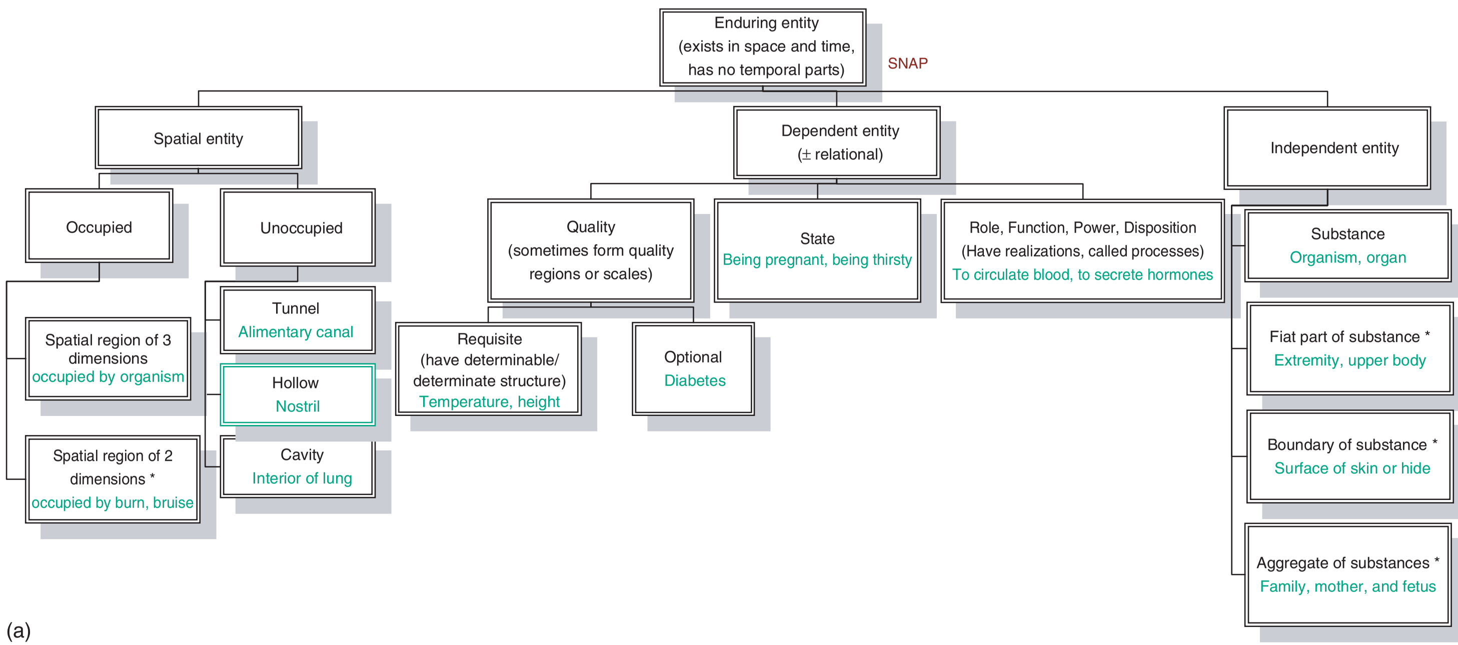

Figure 4 Top-level categories of the (a) SNAP and (b) SPAN ontologies of Basic Formal Ontology (BFO)

(b)

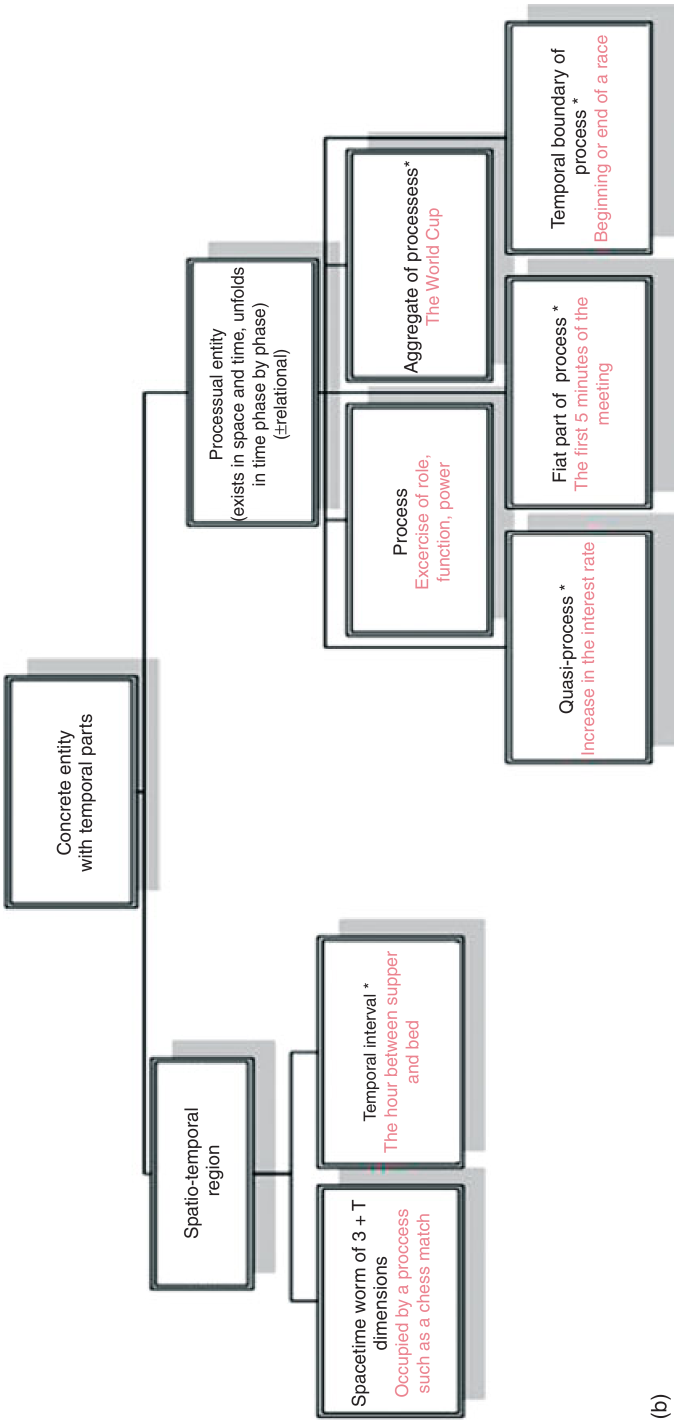

Figure 4 (*continued*)

3. What is an ontology?

Three conceptions of domain ontologies can be distinguished:

1. A concise and unambiguous description of principal relevant entities with their potential, valid relations to each other (Schulze-Kremer, 1998).
2. A system of categories accounting for a particular vision of the world (Guarino, 1998).
3. A specification of a conceptualization (Gruber, 1993).

(1) and (2) represent a view of ontology broadly in the spirit of Aristotle's ontology and of traditional philosophical ontology, and realized in the top-level category systems illustrated above. (3) rests on a view of ontologies rooted in logic-based knowledge representation; it tells us that to build an ontology we must analyze our domain of interest and represent the basic concepts that are exemplified therein in some formal language. Although this describes in broad terms some of what is involved in ontology development, the definition itself does not yet go far enough, and we here specify some further requirements that a domain ontology should satisfy.

1. Each term in an ontology should be defined as precisely as possible. Definitions are the basis for establishing the relations between terms in an unambiguous way and are indispensable when laying down the foundation of an ontology. But writing good definitions is often very hard (not least in the domains of the life sciences). How detailed does one have to be in specifying the concept at hand to make it distinguishable from others already present and those that are to be added in the future? Since this question cannot be answered a priori, definitions frequently need to be updated and such updating should be supported by ontology editing software.
2. The set of concepts covered by an ontology must comprehend all the categories instantiated by the entities in the application domain at the pertinent level of granularity.
3. There should be a specification of the structure or organization of an ontology. This can be by means of an ontology representation language such as KIF (Genesereth and Fikes, 1992) or DAML + OIL (Joint United States/European Union ad hoc Agent Markup Language Committee, 2001; *see also* Article 92, **Description logics: OWL and DAML + OIL**, Volume 8), or it can be a semiformal or informal specification, for example, utilizing UML (Unified Modeling Language) diagrams or natural language.
4. An ontology should be associated with documentation specifying its expressive capabilities, as well as its scope and the levels of granularity of the entities with which it deals.
5. Standardized procedures should be defined specifying how to add, modify, or remove categories.
6. Indications should be given specifying how the ontology and its categories can be used, for example, what kind of inference is supported, how it can be applied, for example, to support information retrieval.

4. Components

The building blocks of an ontology are as follows:

1. *Terms* are the atomic building blocks of an ontology conceived as a syntactic structure.
2. *Links between terms*, for instance, the link between “mammal” and “animal”, representing the fact that the class designated by the former term is included as subclass within the class designated by the latter.
3. *Predicates*, for instance, TRANSCRIBED-BY, CATALYZED-BY, IS 2-DIMENSION.
4. *Propositions* are definite statements about (parts of) the world, sometimes encoded in an ontology representation language and typically representing relations between classes. They include as a special distinguished group: *axioms*, which are fundamental statements that are assumed to be true and that are given without proof. The set of axioms must be logically consistent. Some propositions can be derived from axioms via logical reasoning.
5. A *logical formalism*, including logical constants such as *and* and *or*, variables, and quantifiers.
6. *Definitions*, which can be divided into real, nominal, and ostensive. Real definitions capture the essence or nature of the entities referred to by the term to be defined: they specify the universal marks, which all instances of a defined category share (Michael *et al*., 2001). Nominal definitions reflect the way a given term is used. They may be analytic, which means that they decompose the concept to be defined into its necessary and sufficient conditions (e.g., bachelor is an unmarried man). Or they may be stipulative, which means that they serve to introduce a new concept (e.g., an alpha-helix peptide is a polypeptide molecule with the following geometry . . . , nonlytic viral exocytosis is the exit of the virion particle from the host cell by exocytosis, without causing cell lysis). Ostensive definitions define concepts by pointing to or by enumerating examples, as when we define “yellow” by pointing to yellow things.

Some principal rules governing the formulation of good definitions are as follows:

- Definitions should not be negative in form, for example: *protein is not made of DNA*.
- Definitions should not be too broad. Thus, *proteins are chemicals* is to be rejected.
- Definitions should not be too narrow. *Proteins are covalent strings of amino acids* is to be rejected because it does not embrace posttranslational modifications and quaternary structure.
- Definitions should not be circular (*A protein is made of a protein chain*). Definitions should not convey extra or redundant information. Consider, for example, *regulation of protein catabolism is any process that modulates the frequency, rate, or extent of the breakdown into simpler components of a protein by the destruction of the native, active configuration, with or without the hydrolysis of peptide bonds*.

In addition, we have that in the world toward which an ontology is directed. This includes:

1. The *classes of entities* in reality to which terms refer. These are generalizations of instances, for example, *gene, protein*, and are connected with each other inter alia by the SUPERCLASS-OF and SUBCLASS-OF relations. Often, SUBCLASS-OF is also called IS-A. If one class stands in an immediate SUBCLASS-OF relation to a second class, we say that they stand in the relation of *child* to *parent*; two classes with the same parent are called *siblings*; classes with no children are called *leaves*; a class with no parents is called a *root*.
2. These are *entities* themselves, that is, the instances of classes that are individuals (such as this organism or this sample of protein) connected by the IS-OF-TYPE relation to at least one class. Normally instances play a role only generically – thus, we define the PART-OF relation between classes as follows:
3. *A* PART-OF *B* = def. All instances of *A* are such that there is some instance of *B* of which they are a part (Smith and Rosse, 2004).
   However, specific experiments or specific research findings may enjoy a biological significance and may be referred to explicitly in a corresponding domain ontology (e.g., Mutated-HeLa-Cell-Sample, *E. coli*-R12-Batch-001-DNA-Sequence).
4. *Attributes* and *Relations* to which the predicates refer.

5. Distinguishing marks of ontologies

An ontology is to be distinguished from *a knowledge base* conceived as a *collection of statements of fact.* Rather, an ontology is a specification of the principal categories instantiated by the entities in a given domain of reality and at a given level of granularity. Thus, one might say that an ontology is a certain highly general type of knowledge base filled with knowledge about categories and their ontological relations.

An ontology is to be distinguished from *a model of an application domain*; rather it is a compendium of the building blocks of such domains together with their valid modes of combination, the whole formulated as a theory.

An ontology is *not a database schema*, that is, it does not describe the categories, data types, and organization in a database. Rather, it is a specification of the classes and relations among entities in the real world. Such datatypes may represent such classes and relations also, which means that a database schema can be derived from an ontology by adding data type information and translating the knowledge representation formalism into a database management format. A database schema can also be used as a starting point for ontology building. The corresponding entity types and attributes can then be taken as an initial set of categories to populate an ontology.

An ontology is *not a taxonomy* that knows only about superclass and subclass relations; an ontology is open to other types of fundamental relations, including temporal, mereological (part-whole), topological, compositional, and casual relations, as well as dependence relations, for example, between qualities and functions and the objects which they are the qualities and functions of.

An ontology is *not a vocabulary* or *dictionary* or *thesaurus,* since all these lack the logical organization that an ontology demands in order to support computational inference. Moreover, they standardly do not describe the hierarchy and relations between the entities designated by the terms they include. In an ontology, one can follow a path from any term to any other along the edges of some IS-A hierarchy or by following other relations.

An ontology is *not a semantic net*. Rather, a semantic net is one sort of formalism that can be used to represent ontologies, but this formalism can be used for other purposes also.

6. How to build an ontology?

There are several ways to build an ontology, some of which are surveyed in Fernandez *et al*. (1997). A currently popular methodology, especially in the biological and medical domains, is text mining (Maedche and Staab, 2003; Kashyap *et al*., 2003). Here we describe the method used in Schulze-Kremer (1998).

In order to assemble the components described above (terms, propositions, axioms, formalism, subclass relations, etc.), we apply the following steps in succession:

- Collect an initial list of domain-relevant terms. These can be taken, for example, from database tables or textbooks. This list will have to cover the main central objects and processes in that application domain and will further be extended when populating the ontology.
- Provide a unique and explicit definition for each high-level term. This definition must be precise enough to discriminate the reference of that term from all other entities referred to in the ontology and it should be detailed enough to provide a clear representation of the term's meaning. Experts often have only a tacit understanding of the technical terms they use; thus, it is often difficult to provide an explicit formal definition, not least given the ambiguities by which many terms are affected. Ontology management software should therefore be capable of disambiguating terms with multiple meanings, for example, by imposing unique identifiers.

With the move to lower-level terms as the details of an ontology are filled in, we need to add subclasses to classes already recognized. Here, it is important to fix upon and to use consistently and explicitly one and only one discriminating criterion for each superclass. When this design principle is followed, the ontology automatically manifests the properly hierarchical structure of a tree of subclasses that can also be used as a decision tree when adding or searching for terms. To use the hierarchical tree of subclasses, one starts at the single top-most node and applies the discriminating criterion at each level to the new term. Depending on the characterization of the new term with respect to the discriminating criterion, a decision is reached as to which subclass to follow. For full expressivity, this will require a choice among a number of inheritance modes (e.g., multiple distinct inheritance, where the subclass can be distinctly interpreted depending on its parent

types, e.g., *queen*, seen as a monarch or as a piece on the chess board; or combined cumulative inheritance, where all properties of all parents are inherited by the child term, e.g., a protein-DNA complex inherits features from both DNA and protein). Ideally one should use the same classification criterion throughout the ontology, as is done in the Foundational Model of Anatomy, where the single criterion of *structure* is used (Rosse and Mejino, 2003).

- Be explicit about the disjointness of subclasses, that is, state where subclasses of a single class can or cannot overlap. For example, the distinction of molecules into pure protein and DNA is disjoint, since no molecule can be both at the same time. This greatly helps to focus searches through the subclass hierarchy, since if it is known in advance that a subclassification is disjoint, then only one of its subclasses need be followed when proceeding further down the hierarchy. Using only disjoint subclasses is also called the "single inheritance" mode and implies the creation of a true hierarchy with no fusion between branches as one moves down the tree to more specialized classes.
- Obtain complete connectivity via SUBCLASS-OF relations (or their inverses) from any one term in the ontology to any other term. Thus, at least one SUBCLASS-OF relation (or its inverse) must exist for each term. In this way, we ensure that all terms are defined consistently in such a way as to form a single ontology with no separate ontological islands, which would require integration later on.
- Use one root node only. This root must be general enough to embrace the entirety of the domain-relevant categories, since otherwise different conflicting lineages could emerge.
- Add background knowledge for each term to express domain-relevant properties, but keep this strictly separate from the definitions. The attributes and relations should themselves be reified first (by adding corresponding terms to the ontology) for maximal inference capability.
- Add links from terms in the ontology to other ontologies, natural language dictionaries, database keywords, and so on, thereby interfacing the ontology with applications of various types and supporting its integration with other information sources.

6.1. Guidelines on syntax

The following have emerged as rules of good syntactic practice that serve to make an ontology more manageable for human users.

- Use singular rather than plural forms in a term name.
- Use lower case letters only for terms for classes.
  - Names of instances should begin with a capital letter, for example, *E. coli*-Strain-K12-Sequence.
  - Acronyms should be upper case throughout.
- Observe syntax requirements of the selected representation formalism.
  - Quotes, hyphens, and so on, may be required or forbidden.

  - Unique names may be required by the representation formalism.
- When naming a subclass, start by specializing the name of the superclass.
  - The specializing text should be appended, not prepended.
  - This makes the term easier to be recognized.
- Always provide aliases where known, and keep records of equivalences.

If these rules are followed, this means that when adding a new term one can use the discriminating criteria of the ontology as a decision tree to travel down from the root and at each branch deterministically decide where each new term should belong. One then either finds that the term is already there (possibly under another name), and the insertion process consists merely in the addition of another alias to the existing term, or one ends at some point in the hierarchy where no appropriate superclass can be found. This is then the place where the new term should be added, either directly or by introducing intermediary terms designed to separate the already existing terms and branches from the branch to be newly created. This also guarantees that the ontology remains consistent after a new term has been inserted. Searching for a known or even unknown term can be done in the same way, that is, by traversing the decision tree of discriminating criteria.

There are several difficulties to be overcome when building an ontology. Some difficulties are inherent to the ontology building process, others reflect specific application areas. First is the problem of determining the best (e.g., most informative) criterion of subclassification for a given class. Here one faces, to some degree, an arbitrary decision as to how to proceed in creating subclasses, and this implies that there will, in general, not be one single optimal ontology for a given domain at a given level of granularity but rather only ontologies more or less well integrated with other information resources, having greater or lesser reasoning power, and so on. Also, since the information content of the terms that will need to be added to an ontology in the future cannot be known in advance, the choice of subclassifying criteria may lead to a more complex inheritance structure than necessary, and may thus itself have to be revised.

Other difficulties arising in the ontology building process are the following:

- For many application domains, it is unrealistic to aim for exhaustiveness of an ontology. However, each domain ontology must cover all entities that are of practical relevance for its application domain.
- The arity of relations may be a source of confusion.
  - Relations may be 1:1 (e.g., each person has a social security number that is unique to that person) or 1:Many (e.g., each single person has one weight under standard conditions but several people may have the same weight).
  - There are also 1:Many relations (e.g., a fountain pen writes in a single color but one color may be used by several pens) and Many:Many relations (e.g., a shirt may have several colors and each color may be present in several shirts).
- There is the danger of overelaborating an ontology by getting lost in those branches that are already well understood and thus face few representational difficulties, but which are of little relevance to applications.
  - Therefore, avoid superfluous ontological elements.
  - Check whether all details are really relevant to the intended purpose.

- Storing important data as free text or in comment fields rather than as defined terms can lead to confusion since free text fields are not well accessible for automatic reasoning. Thus, wherever possible one should encode the quality with which to annotate another term as a term itself in the ontology, thereby making its scope explicit and enabling links to its inverse and other relations.
- Multiple inheritance should be carefully applied to make sure that the resulting subclasses really exist as genuine classes. Single inheritance is generally safer and easier to understand.

Of the domain-specific difficulties in ontology building, ill-defined technical terms, controversial technical terms, difficulty of analyzing and separating homonyms, imprecise or lacking documentation of database categories are the most common.

The degree of abstraction and detail one chooses to adopt in building an ontology of a given domain at a given level of granularity determines the practical quality of the ontology, which results in a range from useless (too abstract, only upper-level terms defined that do not give sufficiently detailed information) to impossible to complete (ultimate granularity by going to the finest level of detail irrespective of application needs).

7. Ontology integration

Ontologies can be distinguished according to choice of axioms, which reflect those highly general background beliefs that are taken for granted by those working in the corresponding field. They can also be distinguished by the level of detail in the terms and definitions used and by the choice of subclassifying criterion. All these decisions should be stated explicitly. Important, too, is choice of *domain* – which can extend from single cell to whole populations of organisms – and of *granularity* (from molecule to whole organism).

Given these distinctions, the goal of constructing one comprehensive ontology for the life sciences begins to seem like an unreachable goal. Many groups have thus concluded that they must rest content with several smaller task-oriented ontologies, although the question is still being extensively debated in the bio-ontologies community (Bio-Ontologies Workshop, 2004). However, the approach of building smaller ontologies must eventually come to terms with the goal of combining ontologies together, for example, via techniques for ontology integration of the sort outlined in Ceusters *et al*. (2004). Such integration is by no means a simple matter, for given the heterogeneity of the domain ontologies contained in a system like the UMLS (Lindberg, 1990; *see also* Article 81, **Unified Medical Language System and associated vocabularies**, Volume 8), the relevant integrating steps can hardly be carried out automatically. Each concept must be located and identified in the various subdomain ontologies on the basis of manual search and comparison of definitions, and decisions must be made whether concepts are similar enough to be merged or if several similar concepts need to be defined and cross-related. The corresponding concepts must then be added to a new ontology that will incorporate all subdomain terms within a single consistent framework.

In the special case where the top-level terms of one ontology exactly match with those of another ontology, the corresponding branches can be merged. However, in this case, the data format (syntax, representation formalism) and the relations between terms of the two ontologies still need to be verified and if necessary, manually cross-calibrated.

Since this process of manual ontology integration is quite cumbersome, it might be more sensible to start of with an ontology that has a rather general upper level and can accommodate all of the diverse ontological types that are to be expected from the application domain. This was exactly the motivation for starting the MBO ontology described in Schulze-Kremer (1997).

8. Applications of bio-ontologies

Ontologies can provide computer programs with a counterpart of much of the commonsense background knowledge that human experts bring to bear in processing information. The range of applicability of ontologies is thus rather broad, and two examples, database integration and data annotation, will be discussed here briefly.

Data annotation is the process of linking data records, for example, in a gene product database to other knowledge resources, for example pertaining to cellular locations, in a process comparable to the process of indexing or cataloging books or other literature items. It is not a full-fledged ontology as described above that is required for this purpose, but rather only a controlled vocabulary, whose main purpose is to provide a fixed and unambiguous terminology for communication of research results. A controlled vocabulary of this sort is developed in the Gene Ontology (GO) project (Ashburner *et al*., 2000; *see also* Article 82, **The Gene Ontology project**, Volume 8), which attempts to ensure consistency in gene product annotations by means of the so-called GO identifiers (GO ID). This means that new concepts get new GO IDs, old concepts keep their GO IDs even if they are moved to another location within the hierarchy, and GO IDs of deleted concepts are not reused. As an ontology, GO has a rather simple, informal structure, which rests on the use of only two kinds of links: IS-A and PART-OF.

The GO approach has brought considerable benefits:

1. Work on populating GO could start immediately, without its authors needing to solve some of the intricate problems that face ontologies formalized as logical theories.
2. Extending GO does not require the completion of complex protocols of formally determined steps but can be done intuitively by the expert biologist.
3. There are few formal constraints standing in the way of easy incorporation of existing biological terms into the GO vocabulary.
4. The principle of unique identifiers allows GO terms to be used for database annotation without the consideration of their place in the GO hierarchy.

Focusing on the rapid population of GO has, however, a number of drawbacks (Smith *et al*., 2004):

1. It is unclear what kinds of reasoning are permissible on the basis of GO's hierarchies.
2. The rationale of GO's subclassifications is unclear. The reasoning that went into current choices has not been preserved and thus cannot be explained to or reexamined by a third party.
3. No procedures are offered by which GO can be validated.
4. There are insufficient rules for determining how to recognize whether a given concept is or is not present in GO. The use of a mere string search presupposes that all concepts already have a single standardized representation, which is not the case.

9. Open biomedical ontologies

GO is a part of the Open Biomedical Ontologies (OBO) project (**http://sourceforge.net/projects/obo**), which offers a framework for the development of well-structured controlled vocabularies for shared use across different biological domains. Contributions to OBO obey the following guidelines:

1. The ontologies must be open source, which means that they may be used by all without any constraints other than that their origin is acknowledged and they not be redistributed in altered form. OBO ontologies are intended to be resources for the entire biological community.
2. The ontologies employ, or can be instantiated in, or can be easily converted into, a common shared syntax. This may be either the GO syntax, extensions of this syntax, or OWL. This criterion is not met in all of the OBO ontologies currently listed.
3. The ontologies are orthogonal to other ontologies already lodged within OBO. Thus, different ontologies, for example, ontologies for anatomy and process, can be combined through additional relationships, and the latter can then be used to constrain when terms from different ontologies can be jointly applied to describe one and the same biological entity from distinct perspectives.
4. The ontologies share a unique identifier space. The source of concepts from any ontology can be immediately identified by the prefix of the identifier of each concept. It is, therefore, important that this prefix be unique.
5. The ontologies include textual definitions of their terms. Many biological terms are ambiguous; thus, each term should be defined in such a way that its precise meaning within the context of a particular ontology is clear to a human user.

10. Resources on (bio-)ontologies

The following include information relevant to work on bio-ontologies.

- Protégé 2000, an ontology editing software from Stanford Medical Informatics (*see* Article 91, **Frame-based systems: Protégé**, Volume 8), is at **http://smi.stanford.edu/projects/protege**.

- GKB Editor, the Generic Knowledge Base Editor of Peter Karp and SRI can be found at **http://www.ai.sri.com/~gkb**.
- OilEd, a simple ontology editor, resides at **http://www.ontoknowledge.org/oil/tool.shtml**.
- The Semantic Web Community Portal at **http://www.semanticweb.org** has lots of ontology-related information and pointers.
- Ongoing KBS/Ontology Projects and Groups are listed at **http://www.cs.utexas.edu/users/mfkb/related.html**.
- On-To-Knowledge: Content-driven Knowledge-Management through Evolving Ontologies is a European funded research project at **http://www.ontoknowledge.org**.
- The previous Bio-ontologies Workshops and other material on ontologies is compiled by Robert Stevens at **http://img.cs.man.ac.uk/stevens**.
- Cycorp has its own webpage at **http://www.cyc.com**.
- Formal Ontology in Information Systems is an international conference series on ontologies with a webpage at **http://www.fois.org**.
- Barry Smith has an extensive collection of works on ontology development in general and biomedical ontologies in particular at **http://ontology.buffalo.edu/smith**.

Specialist Review

Unified Medical Language System and associated vocabularies

Christopher G. Chute
Mayo Clinic College of Medicine, Rochester, MN, USA

1. Introduction

1.1. Terminologies, vocabularies, and ontologies

Biology and medicine, like most sciences, generate new knowledge and understanding by careful and systematic analyses of observations, outcomes, and experimental evidence. In the case of clinical medicine, these "experiments" are often cast in the form of epidemiologic outcomes research, which comprises a kind of "natural experiment". However, to represent biological and clinical observations in a fashion that can sustain analyses, these observations must conform to a system of weights and measures suitable to inferencing. Unlike absent metrics akin to meters, seconds, and grams, biology and medicine invoke well-controlled terminologies to provide consistent and comparable representations of biological functions, abnormal functions, and genomic variation. Clinical medicine in particular extends these characterizations to include pathologies, disease states, and syndromes.

The representation of biomedical data in the form of comparable and consistent concepts poses all the logistical and philosophical problems confronted by the knowledge representation community within the artificial intelligence specialty of computer science. It should not be surprising, then, that the sophistication of biomedical terminologies ranges from enumeration of concepts intended to populate "pick lists" for data entry to highly formal, description-logic-based ontologies. Indeed, within the ontology and knowledge representation communities, practical examples of sophisticated ontologies used by a broader community are most frequently found within biology and medicine.

The terms vocabulary, terminology, and nomenclature are often used interchangeably. While technical differences discriminate these terms, the more relevant distinction is between these three terms and ontology. Ontology has evolved to mean a catalog of well-formed, internally consistent, and explicitly interrelated concepts that cover a specific domain, such as anatomy or gene functions. Virtually all formal ontologies today are constructed using description logics, a family of first-order predicate logic subsets that are computationally tractable using reasoning algorithms. These description logics are used not only to define concepts in

terms of other concepts and their relationships, such as "part of" or "kind of," but also to assert knowledge-class relationships, such as

"Myocardial infarction" has_location "wall of the heart".

The fundamental dependence of biology and medicine on well-controlled terminologies, simple or complex, has caused a proliferation of terminology efforts. These terminologies have greater or lesser degrees of overlap, redundancy, consistency, and rigor. Not infrequently a researcher may wish to invoke a preexisting "catalog of terms" or even a more formal ontology in the conduct of large-scale experiments, clinical protocols, or randomized trials. Any resource that can transform a search for an appropriate terminology or ontology from a hit-or-miss exercise into an efficient and effective process would obviously be welcome. The Unified Medical Language System (UMLS) of the National Library of Medicine (NLM) was designed and has evolved to be the resource of choice in finding and working with biomedical terminologies.

2. History and origins of the UMLS

In 1984, a collaborative project among academic contractors to the National Library of Medicine began to consider how to contain and interrelate major biomedical terminologies. Mark Tuttle, a protégé of the late Scott Blois at the University of California, San Francisco, is widely credited with promoting the entity-relationship design of ASCII data tables that became ultimately adopted as the first information model for the industry in 1988. The first version of the Metathesaurus contained a few hundred thousand English language terms drawn from little more than a dozen terminologies. By 2005, the UMLS contained more than 1 million concepts and 5.6 million unique concept names from more than 100 different source vocabularies with representations in 16 languages.

The original Metathesaurus, the core collection of terminologies within the UMLS, was often referred to as the "Rosetta stone" of biology and medicine. An early goal of UMLS was to facilitate mapping of concepts between and among the many terminologies, such as the MeSH (Medical subjects heading) codes used in PubMed and the ICD (International Classification of Disease) codes used throughout clinical medicine. Over time, this ambitious goal was replaced by the UMLS providing the basis for medical informatics research about terminologies, a primary source for ontological relationships among concepts, and a major reference source for natural language processing, with a focus on identifying biomedical concepts and text.

Today, the NLM publishes that "The purpose of . . . [the] UMLS is to facilitate the development of computer systems that behave as if they 'understand' the meaning of the language of biomedicine and health". While this is a broad and abstract goal, the NLM has enjoyed substantial success in having the UMLS broadly adopted throughout the medical informatics research community as a basis for medical concept and natural language processing research. Increasingly, the basic biology, electronic medical record, and clinical systems communities are recognizing the substantial inherent value that the UMLS has accumulated.

2.1. Methods and formats

In the nearly two decades that the UMLS has been published, its presentation, data formats, information model, and syntax have undergone numerous changes. Ranging from experiments with unwieldy and unscalable ASCII flat files of fully denormalized data to the elegant but obscure ASN.1 (Abstract Syntax Notation) formatting, the UMLS has always had as its core a family of vertical-bar (|) delimited ASCII tables of terms, concepts, and relationships.

In 2004, the NLM introduced a dramatic overhaul of UMLS representation called the Rich Release Format (RRF). The RRF is intended to capture the more complex annotations and relationships present in sophisticated ontologies, specifically SNOMED-CT, which had become available in the United States under an NLM-brokered national site license. The primary motivation for introducing the RRF syntax was to achieve "source transparency" between a publisher's version of an ontology and that represented within the UMLS. This implies that an extraction of a terminology from the UMLS should be computationally identical to that distributed by the publisher. NLM sought, in their words, "to represent the detailed semantics of each source vocabulary exactly". The NLM and the College of American Pathologists (publisher of SNOMED-CT) concur that the UMLS has achieved source transparency for SNOMED-CT.

3. UMLS resources

The NLM's UMLS represents a suite of resources, ranging from a core catalog of concepts drawn from many terminologies (the Metathesaurus) to highly specialized natural language-processing tools within the Specialist Lexicon component. The major components are outlined here, though the number and persistence of minor components have varied over the lifetime of the UMLS project. Many references to the UMLS confuse the entire suite of resources with the Metathesaurus. This confusion is likely to persist, since many authors continue to refer to the Metathesaurus as the UMLS – implying that the Metathesaurus is the entirety.

3.1. Metathesaurus

The Metathesaurus of the UMLS has remained the core component of the system since its inception. Comprising a common representation of more than 100 terminologies, the Metathesaurus has emerged as an invaluable resource to anyone with a need for biomedical ontologies. The Metathesaurus can be best understood by outlining how concepts are represented in a common format, and then how relationships and attributes about these concepts are represented.

It is important to realize that with few exceptions, concepts do not exist in the Metathesaurus unless they are imported from one of the source terminologies. As such, the Metathesaurus does not comprise an ontology created and maintained by the NLM, but rather a synthesis of many code systems, terminologies, nomenclatures, and ontologies in a common format. Furthermore, the NLM

faithfully represents the semantic hierarchies and relationships contained in these source terminologies; such fidelity, not infrequently, results in ambiguous and occasionally contradictory assertions about concepts. As a practical matter, the NLM has established good relationships with the editors and maintainers of the major source vocabularies. Over time, such relationships have led to far fewer contradictions and less ambiguity. However, the Metathesaurus is a general-purpose resource, which typically must be adapted or constrained for specific applications.

3.1.1. Concepts

The representation of concepts in the Metathesaurus centers around several related but purpose-specific identifiers:

Concept unique identifier (*CUI*): The Metathesaurus defines as its core semantic unit the notion of a concept. Many different terms can mean the same thing, and thus be regarded as the same concept. The UMLS enforces a rigorous definition of synonymy; however, synonymous concepts across different source terminologies may not have identical ancestries.

Lexical unique identifier (*LUI*): The Metathesaurus distinguishes terms with similar appearance from synonyms to a concept. The NLM collapses text strings that differ in inflection, plural form, capitalization, and occasionally word order into a common lexical unit. However, this collapse is based on syntactic similarity alone; specifically, terms that share a lexical form may be asserted to have different meanings (CUIs) in their source terminologies.

String unique identifier (*SUI*): The string identifiers in the Metathesaurus preserve literal differences in text strings as they occur in the source vocabularies. Thus, many SUIs will typically map to one LUI. SUIs, as with LUIs, may be mapped to more than one CUI (concept) owing to assertions about their meanings that may differ across source vocabularies.

Atom unique identifier (*AUI*): The atom identifiers are a new innovation within the RRF representation of the Metathesaurus and correspond to a single instance of a string within a source vocabulary. Identical strings, that is, the ones with an equivalent SUI, may exist within a single source because a string may play different contextual roles for which it would be assigned unique atom identifiers. Obviously, many atoms might exist across different terminologies with identical string (SUI) forms. However, atoms are assigned one and only one CUI, since an atom may have only one semantic interpretation within a given source.

3.1.2. Relationships

Relationships among entries in the Metathesaurus are of two fundamental types: (1) the hierarchical relationships typically of the "is_a" variety (though these can occasionally include partonomy or "part_of" relations) and (2) asserted relationships. Hierarchical relationships, including sibling relations, are explicitly represented in the Metathesaurus using relational (in the database sense) tables.

Finally, most relationships about entries within a terminology derive from the source terminology itself. Relationships across terminologies, with the exception of synonymy, are not uniformly asserted by the NLM, though many such relationships

do exist. However, a special class of relationships that captures information about well-curated "mappings" between concepts across vocabularies is emerging. An example would be the mapping of SNOMED-CT terms to the International Classification of Disease (ICD).

Relationship unique identifiers (RUI): All relationships in the Metathesaurus are assigned a unique identifier, in part to facilitate version management over time.

Attribute unique identifier (ATUI): An attribute about a Metathesaurus entry provides additional information about that entry. Attributes may apply to concepts, atoms, or relationships. They may include highly generalizable information about a concept, such as a source-asserted definition, or fairly parochial meta-data relevant only to a source vocabulary, such as the date an atom was last edited. Attributes form a large class of information about Metathesaurus entries and can include computable characteristics, such as Semantic type (drawn from the Semantic Network, below), or the human language in which a string has linguistic meaning.

3.1.3. Major source terminologies

The relevance and appropriateness of a source are invariably dependent upon the user. However, some generalizations can be drawn by looking across the spectrum of terminologies that comprise the Metathesaurus, particularly with respect to clinical versus basic science emphasis. The heritage of the UMLS arose from a dominantly clinical legacy, as measured by the nature of source terminologies throughout its history. However, in the recent past, this is changing with the inclusion of sources aligned with the interests of biologists and basic scientists, such as the Gene Ontology (GO) or the Foundational Model of Anatomy (not yet included in the Metathesaurus).

Medical subjects heading (MeSH): The core indexing vocabulary underpinning Index Medicus, Medline, and PubMed, MeSH has reflected the contents of the published literature in biology and medicine for decades. Sometimes underrated and often undervalued, MeSH is a well-formed ontology whose original structure and elegance predates description logics and even the relational data model. MeSH uniquely traverses the content areas of cutting-edge science and standard medical practice. MeSH contains about 22 500 concepts and is fully represented in the Metathesaurus in about 560 000 row entries.

International classification of disease, 9th revision, clinically modified (ICD-9-CM): The International Classification of Disease, revised by the World Health Organization (WHO) on a schedule of decades, has been extensively modified from its original mortality application for clinical description and morbidity in the United States. Its primary use is for insurance and Medicare reimbursement in the United States, and it has limitations associated with being a code for financial billing. Nevertheless, ICD-9-CM remains ubiquitous in clinical settings, the primary coding system for hospital-based disease profiling, and widely reused for disease registries and patient databases. Domain concept headings for diseases and surgical procedures are enumerated in the Metathesaurus and comprise about 20 000 row entries.

Systematized nomenclature of medicine – clinical terms (SNOMED-CT): SNOMED is a comprehensive vocabulary of diseases, pathologies, clinically relevant organisms, symptoms, and related terms, with a 40-year heritage of development by the College of American Pathologists. In 1999, SNOMED merged with the broadly based Clinical Terms Version 3 (formerly the Read Codes) of the UK National Health Service; the merged effort became SNOMED-CT. In the mid-1990s, SNOMED began to adopt description logic underpinnings, which have expanded and become more robust over time. While not yet a formal ontology in the computer science sense, it is widely regarded as the largest and most complete body of clinical concepts available. SNOMED contains approximately 360 000 concepts with 1 million associated terms and 1.5 million relationships.

Gene ontology (GO): The Gene Ontology is a compilation of concepts about molecular function, biological process, and cellular components created by biologists for biologists. It began as a consortium among the fly (Drosophila), worm (Saccharomyces), and mouse model communities in 1998, and is now a collaborative among 16 organizations coalescing around the Open Biomedical Ontology (OBO) projects. Significant efforts are in progress to evolve the Gene Ontology into a formal ontology. GO contains approximately 17 000 concepts among 22 000 terms.

National drug files – reference terminology (NDF-RT): The US Department of Veterans Affairs (VA) has maintained a comprehensive catalog of drugs and pharmaceuticals used throughout the VA hospital system. Beginning in 2001, efforts were made to formally link drugs and drug classes in an ontology structure. The NDF-RT data model comprises enumerations and relationships among active ingredients, drug components, clinical drugs, finished dose form, drug products, packaged drugs, and associated taxonomies. These taxonomies include mechanism of action, physiologic effect, therapeutic intent, drug class, chemical structure, pharmacokinetics, clinical indications, and dosage form. The terminology contains approximately 38 000 drugs descriptions and 4000 drug classes.

Orderable drugs, normal form (RxNorm): RxNorm is part of the collaboration among the Food and Drug Administration (FDA), the Department of Veterans Affairs, and the National Library of Medicine to work on a common drug model and suite of terminologies. The model is outlined in the NDF-RT description above; RxNorm comprises the clinical drugs, finished dose form, and drug products component of that model. The NLM maintains RxNorm, which presently contains nearly 140 000 terms about 110 000 distinguishable drug forms.

3.2. Semantic Network

The Semantic Network is the core component of UMLS, which enumerates the underpinning semantic types and type relationships of the Metathesaurus. Unlike the Metathesaurus, the Semantic Network is entirely authored and maintained by the NLM; it depends on no source terminologies for its contents. As a consequence, the Semantic Network is highly generalizable. Every concept from every source in the UMLS Metathesaurus has at least one semantic type drawn from the Semantic Network. These assignments are asserted by NLM content editors.

Compared to the Metathesaurus, the Semantic Network is quite small. It contains only 135 concepts or semantic types, which are interrelated with 54 different semantic relationships. However, the sophistication of this resource should not be estimated from its size. The inheritance hierarchy and interrelationships are highly specified. The assignment of semantic type to Metathesaurus concepts enable inferences about concepts from different source terminologies, by reference to inheritance and relationships in the semantic network.

Examples of semantic types within the network include physiologic function, disease or syndrome, and genetic function. Semantic relationships, which have their own hierarchy, include "affects", which in turn has its own children, for example, manages, treats, disrupts, complicates, interacts with, and prevents.

An enhanced feature of the Semantic Network is the explicit sanctioning of appropriate inheritances through a mechanism the NLM describes as "blocking". For example, the semantic type "mental process" has a theoretical ancestor in the form of "Plant". Since plants are not capable of mental processes, given the definition of those concepts in the semantic network, this theoretical inheritance is explicitly disallowed or blocked.

To the extent that the UMLS Metathesaurus can be considered to assert a cohesive ontology about biology and medicine, the root nodes of such a metaontology are the semantic types within the semantic network. Similarly, the ontological relationships among the hundreds of thousands of concepts in the Metathesaurus can be viewed at the metaconcept level by the relationships among semantic types asserted in the Semantic Network.

3.3. Specialist lexicon

The content-oriented resources of the UMLS, including the Metathesaurus in the semantic network, have enormous potential for application in data entry systems, electronic health records, research databases, and enterprise vocabulary systems. A classical barrier between the effective application of UMLS resources and the community of potential users is the human user interface problem. Accurately typing long and complex biomedical terms, or attempting to sort among thousands of items on a pick list is not an attractive prospect to most humans. The NLM recognizes that the effective access and use of UMLS knowledge sources is contingent upon underpinning tools and lexical resources that can effectively map human natural language to terminological concepts. The Specialist Lexicon is an English-language-centric effort to provide precisely such a resource.

The specialist lexicon is divided into two fundamental components: (1) a comprehensive lexicon of biomedical terms and their functional variance and (2) suites of open-source, Java-based tools for manipulating words, language, text, and spelling.

3.3.1. Lexicon

The comprehensive lexicon draws unique words and terms from the Metathesaurus, and extends this word list with linguistic, syntactic, and inflectional information about these words. For example, verbs are annotated as to whether or not they

conform to regular inflections, and if they are irregular, their conjugation is specified. Similar data corresponds to case forms for nouns. Additional examples include the modality of pluralization, ranging from Greco-Latin form, to variants on group, regular, fixed, uncountable, and metalinguistic forms.

The Specialist Lexicon is quite rich and sizable, given its focus on biomedical concepts and words. It includes about 470 000 unique words, 500 000 agreement and inflection entries, 310 000 inflection instances, 17 000 abbreviations and acronyms, 34 000 modifiers, 22 000 spelling variants, 33 000 word properties, 81 pronouns, 8000 normalizations, and 2000 trademarks.

3.3.2. Tools

As a component of the Specialist Lexicon, the NLM provides open-source tools that harness the richness and content of the word-oriented lexicons of the UMLS. These tools are widely used throughout the medical natural language processing community, and have become embedded in applications such as terminology servers and electronic health records.

Lexical variant generator (LVG): Lexical variant generator is the core tool for the application of Specialist Lexicon knowledge. The basic tool takes as an argument the kind of variance a user might seek to generate from an input phrase, such as a diagnostic description. Presently there are 26 "flow" parameters that can be specified when using LVG. They include such options as canonicalize, uninflect, tokenized, lowercase, proper name filter, remove plurals, remove genitive, process punctuation, transform to Unicode, spelling variants, synonymy, and sorting. These options can be used to inflate terms to all specified variants or reformat input into a standard normal form.

Normalize word form (Norm): Norm is a callable form of LVG that prespecifies a convenient and standard way of lexically normalizing biomedical terms. The current version strips possessives, punctuation, and stop words, makes all characters lowercase, converts words into their inflection base form using the Specialist Lexicon data tables, and alphabetically sorts all words in the string. A version of the norm program, LUInorm, is the basis on which the Metathesaurus defines lexical identity among term variants. The Norm entry point to LVG is by far the most frequently used application tool in the Specialist Lexicon by application developers, researchers, and those responsible for emerging standards for terminology services in the biomedical community.

3.4. Access, use, and intellectual property

3.4.1. Distribution and formats

Early versions of UMLS were distributed exclusively by CD-ROM. In recent years, physical distribution has required migration to higher-capacity DVD formats. However, most users today – once licensed – obtain UMLS resources via the Internet. The standard URL for the UMLS starting point is **http://www.nlm.nih.gov/research/umls/**.

The NLM provides a sophisticated installation tool and customizing resource called Metamorphosys, which allows users to specify language-specific filters such as English only, which terminologies a user wishes to include in a local installation, a rank order priority of precedence for terminology sources within a local installation, and a rich variety of default subsets and installation scripts. Users may also specify that detailed content extraneous to their application use be suppressed during installation. Metamorphosys is delivered as an open-source tool and precompiled to run in standard computing environments, including Linux, Windows, Mac, and Solaris.

3.4.2. Knowledge source service

The NLM provides and continuously improves a service layer interface to UMLS resources, including the Metathesaurus, Semantic Network, and Specialist Lexicon. The Knowledge Source Server (KSS) permits live browsing of UMLS contents with a highly configurable interface. Additionally, the KSS supports a broad spectrum of API (application programming interface) calls that return concepts, synonyms, conceptual children or ancestors, definitions, and normalized forms.

3.4.3. Licensing issues

Many of the sources within the UMLS are contributed under restrictive license. The NLM therefore requires all users of the UMLS to register and agree to the license terms of the corpus. As a practical matter, more than 65 percent of UMLS concepts in the Metathesaurus have no intellectual property restrictions for general use. The rest of the source terminologies are classified into four categories of license.

Category 1: This is a liberal license that merely prohibits users of the source terminology from producing derivative works based on the source terminology. Users may employ the terms and concepts in research for commercial applications.

Category 2: This license category restricts the use of UMLS-provided concepts that derive from a Category 2 license source from being used for business applications on a production basis. For example, if users wish to use such source information for diagnoses within a hospital electronic record, additional licensing from the terminology provider would be required. However, use of the source material for research or product development is permitted.

Category 3: This is the most restrictive license category, in which the use of UMLS source-provided concepts is restricted solely to internal use for terminological research or product development. All other uses require a licensing arrangement with the source provider.

Category 4: This is a special category of use created to accommodate the circumstances for the US site license of SNOMED-CT.

Specialist Review

The Gene Ontology project

Midori A. Harris, Jane Lomax, Amelia Ireland and Jennifer I. Clark

The European Bioinformatics Institute, Cambridge, UK

1. Introduction

As noted in the introductory chapter (*see* Article 79, **Introduction to ontologies in biomedicine: from powertools to assistants**, Volume 8), ontologies represent domains of knowledge by defining terms used within the domain as well as relationships between them. The organization of knowledge about a given topic into an ontology allows databases to standardize annotations of their contents, improves computational queries, and can support the construction of inference statements on the basis of available information.

In the case of genetic and genomic databases, ontologies can be used to rationalize the storage and querying of information about sequence features and functional attributes of gene products. For example, both biologists and bioinformaticians need to pose meaningful questions such as:

- What is the function (at the molecular level) of a gene product?
- In what larger process(es) does a gene product participate?
- What is the subcellular localization of a gene product?
- Which gene products in one species have the same function as a given gene product in a different species?

These questions, particularly the last, can only be answered easily if both species share a scheme for the functional classification of gene products, with the necessary links between the databases. (*See also* Article 29, ***In silico* approaches to functional analysis of proteins**, Volume 7 and Article 36, **Large-scale, classification-driven, rule-based functional annotation of proteins**, Volume 7 for more information on annotation of protein function.)

The Gene Ontology (GO) project provides a set of ontologies that address the need for consistent, computable descriptions of biological entities, such as genes and gene products, in different databases (Blake and Harris, 2003; The Gene Ontology Consortium, 2000, 2001, 2004). The project is the work of the Gene Ontology Consortium, which includes most prominent repositories for plant, animal, and microbial genome information as well as other, non-species-specific, sequence databases (a complete list of GO Consortium members is available on

the GO website, **http://www.geneontology.org/**). All of the materials produced by the GO project – including the ontologies, gene product annotation sets, and software – are freely available to the public. Because the GO project continues to develop and is far from completion, the GO Consortium welcomes suggestions and contributions from anyone in the biology and bioinformatics communities.

2. The GO vocabularies

The ontologies developed by the GO Consortium cover four nonoverlapping domains of molecular biology. Three of the vocabularies describe attributes of gene products and the fourth describes sequence features.

The GO is designed to be applicable to all species, so each of the ontologies includes all terms falling into its domain, regardless of whether the biological attribute is restricted to certain taxonomic groups. Therefore, biological processes that occur only in plants (e.g., flower development) or mammals (e.g., lactation) are included. GO terms and relationships do not attempt to reflect the structure of gene products, nor represent evolutionary relationships.

Molecular function describes activities at the molecular level, such as catalysis or binding; molecular function terms do not specify where, when, or in what context an action takes place. Examples of individual molecular function terms are the broad concept "kinase activity" and the more specific "6-phosphofructokinase activity", which represents a subtype of kinase activity. A gene product may have a number of molecular functions; for example, myosin would be assigned the molecular function terms "actin binding", "ATPase activity", and "microfilament motor activity". This gene product would therefore be associated with all three molecular function terms. The annotation of gene products to more than one term in an ontology is supported by the GO system.

Within the context of GO, it is important to distinguish activities from the entities (molecules or complexes) that perform the actions. Molecular function terms represent activities, and should not be confused with gene products that have been named after activities they possess. For example, in many cases, a protein whose function is a catalytic activity has been named by that activity ("alcohol dehydrogenase activity" is a molecular function, with a corresponding GO term; "alcohol dehydrogenase" is also the name of a specific protein).

Biological process describes biological goals accomplished by ordered assemblies of molecular functions. High-level processes such as "cell death" can have both subtypes, such as "apoptosis", and subprocesses, such as "apoptotic chromosome condensation". Terms representing the regulation of biological processes are also included in this ontology. Note that a biological process in GO is not equivalent to a pathway; GO does not attempt to represent the dynamics or dependencies that would be required to describe a pathway (*see* Article 88, **Bioinformatics pathway representations, databases, and algorithms**, Volume 8).

Cellular component describes locations, at the levels of subcellular structures and macromolecular complexes. Examples of cellular components include "nuclear inner membrane", with the synonym "inner envelope", and the "ubiquitin ligase complex", which has several subtypes.

More recently, the Sequence Ontology (SO, **http://song.sourceforge.net/**) has been developed to permit the classification and standard representation of sequence features. Defined sequence features include terms such as “exon”, whose meaning is widely accepted, and the more problematic term “pseudogene”, for which several different usages have yet to be resolved. Although the SO is a relatively new vocabulary, and is still undergoing refinement, it is already being used for genome annotation projects in *Drosophila* and *Caenorhabditis elegans*.

3. Vocabulary structure

The ontologies in GO are structured as directed acyclic graphs (DAGs), wherein any term may have one or more parents and zero, one, or more children. Within each vocabulary, terms are defined, and parent–child relationships between terms are specified. A child term is a subset of its parent(s). The ontologies thus capture, for example, the fact that the nucleolus is part of the nucleus, which in turn is part of the (eukaryotic) cell; further, the DAG structure permits GO to represent “endoribonuclease activity” as a subcategory of both “endonuclease activity” and “ribonuclease activity”.

At present, the GO vocabularies define two semantic relationships between parent and child terms: is_a and part_of. In GO, an is_a relationship means that the term is a subclass of its parent. (Note that “is_a” should not be confused with “instance of”; the latter is a specific example of a member of the class; see Odell, 1998; Stevens *et al*., 2000.) For example, “terminal glycosylation” is a subclass of “protein glycosylation”. The is_a relationship is transitive, which means that if “GO term A” is a subclass of “GO term B” and “GO term B” is a subclass of “GO term C”, “GO term A” is also a subclass of “GO term C”. For example,

- glucose metabolism is a subclass of hexose metabolism;
- hexose metabolism is a subclass of monosaccharide metabolism;
- therefore, glucose metabolism is a subclass of monosaccharide metabolism.

The second relationship type in GO, part_of, is semantically complex as employed in the GO system. A discussion of meronomy, the study of the relationship between wholes and parts, is beyond the scope of this article (see Simons, 1987). That said, within GO, part_of may mean “physically part of” (as in the cellular component ontology) or “subprocess of” (as in the biological process ontology). Furthermore, the part_of relationship used in GO is “necessarily is_part”: wherever the child exists, it is as part of the parent. GO does not impose the “necessarily has_part” condition, which would require that wherever the parent exists, it has the child as a part. A GO term may be a part_of child of one parent and an is_a child of one or more additional parents.

The use of only two relationship types limits the expressive power of GO; the GO Consortium anticipates that in the future its ontologies will incorporate more relationship types, which will allow GO to be used more effectively for logical reasoning.

4. Gene product annotation

The GO vocabularies were originally developed to facilitate the functional annotation of gene products. Accordingly, collaborating databases provide data sets comprising links between database objects (which may represent genes, transcripts, proteins, or macromolecular complexes) and GO terms, with supporting documentation. Because a single gene may encode very different products with very different attributes, GO protocols recommend associating GO terms with database objects representing gene products rather than genes. At present, however, many participating databases are unable to associate GO terms to gene products, and therefore use genes instead. If the database object is a gene, it is associated with all GO terms applicable to any of its products, including RNAs and proteins, with all possible splice variants.

GO annotation conventions require that every annotation be attributed to a source. The source may be a literature reference, another database, or a computational analysis. Furthermore, the annotation must indicate the type of evidence the cited source provides to support the association between the gene product and the GO term. A standard set of evidence codes qualifies annotations with respect to different types of experimental determinations. The codes are available on-line (**http://www.geneontology.org/GO.evidence.html**), together with documentation that describes their use in functional annotations. For example, the "inferred from mutant phenotype" (IMP) evidence code indicates that the evidence supporting the association between a GO term and the gene product is derived from the examination of the phenotypic results of a genetic alteration.

Annotations may result from automated or curated operations. The most reliable annotations are those made manually by database curators; these are normally based on curatorial review of published literature and supported by experimental evidence. Curated annotations provide depth and accuracy; curators not only can apply any term from the ontologies, but can also request new terms as needed. Several evidence codes represent types of experimental data, such as "inferred from mutant phenotype" (IMP) or "inferred from direct assay" (IDA), and are extensively used in the manual annotation process. Manually curated annotation sets are now available for gene products in many model organisms (see below for link).

In addition to the curated annotation sets, large sets of electronic annotations made using computational methods have been generated both for model organisms and for many less experimentally tractable organisms, including human. A number of different automated methods have been applied (e.g., Camon *et al*., 2003; Mi *et al*., 2003; Pouliot *et al*., 2001; Xie *et al*., 2002). The evidence code "inferred from electronic annotation" (IEA) is used for all of these automated procedures. One example of this type of strategy is that based on the use of existing properties of the entries, such as the presence of keywords and Enzyme Commission (EC) numbers (Webb, 1992). Mapping of InterPro (Mulder *et al*., 2003) entries to GO terms (described below) also allows further associations of GO terms to entries to be made, on the basis of the presence of InterPro cross-references in other databases. Sequence similarity to well-studied gene products can also be used to generate annotations for large sets of genes or gene products.

A table summarizing annotation status for contributing databases is maintained on the GO website, from which annotation sets can also be downloaded (**http://www.geneontology.org/doc/GO.current.annotations.shtml**). Additional information on GO annotations can be found in references listed in the on-line GO Bibliography (**http://www.geneontology.org/GO.biblio.html**).

5. Other uses of GO

In addition to gene product annotation, GO has been put to a wide variety of uses, many of which were not envisaged when it was first established. One of the most common examples is the use of GO terms and gene product annotations to help interpret the results of large-scale experiments such as microarray studies (*see* Article 90, **Microarrays: an overview**, Volume 4), where GO annotations can reveal which broad biological processes are affected under the conditions tested (e.g., Bonner *et al*., 2003; Hawse *et al*., 2003; Meyer *et al*., 2004; additional references can be found in the on-line GO Bibliography at **http://www.geneontology.org/GO.biblio.html**). Within the biological and bioinformatics communities, other applications of the ontologies include gene function prediction (King *et al*., 2003), collaborative construction and analysis of cellular pathways (Demir *et al*., 2004), and association of genes to genetically inherited diseases (Perez-Iratxeta *et al*., 2002). GO terms have also been incorporated into the Unified Medical Language System (UMLS; *see* Article 81, **Unified Medical Language System and associated vocabularies**, Volume 8) maintained by the US National Library of Medicine (Lomax and McCray, 2004), and have been used to guide the development of a vocabulary for molecular imaging research (Tulipano *et al*., 2003).

GO is also attracting interest in the computer science community. For example, GO has been used as a test of applying description logic (*see* Article 92, **Description logics: OWL and DAML + OIL**, Volume 8) approaches to building sound, complete, and logically consistent ontologies (Stevens *et al*., 2003; Wroe *et al*., 2003), and has featured in research into machine-processable ontologies (Williams and Andersen, 2003) and into the automated checking of ontological consistency (Yeh *et al*., 2003). GO terms also offer a valuable standardized terminological resource to natural language processing researchers, facilitating information extraction from texts, knowledge discovery, and ontology building from large collections of documents (*see* Article 84, **Ontologies for natural language processing**, Volume 8).

6. GO resources on the web

The GO website (**http://www.geneontology.org/**) is the comprehensive resource for users seeking information on the Gene Ontology. It provides the ontologies and annotations, and offers GO-related tools, a full suite of documentation, frequently asked questions (FAQ), mailing lists, and more. The Gene Ontology is a public resource and all data are freely available. The GO ontologies are available in a

number of formats, including the OBO flat file format, XML, and as a MySQL dump, all of which can be downloaded from the GO FTP archive or an anonymous CVS repository. Most of the database groups annotating gene products using GO release their files to the public, and these can be accessed from the website. Other useful resources include archived monthly GO releases, a set of GO slims (described below), and GO monthly reports, which detail what changes have been made to the ontologies. All are available from the Downloads section of the GO website (**http://www.geneontology.org/index.shtml#downloads**).

6.1. GO tools

As noted above, GO has been used for a wide variety of different purposes, and this is reflected in the diversity of tools available. Software is available to navigate, use, and manipulate the GO vocabularies and annotations, and for using GO for specific applications such as microarray analysis and text mining. Several tools are developed and maintained by the GO Consortium itself, of which two are of particular interest: the web-based GO browser AmiGO and the ontology editor DAG-Edit. A full list of tools is available on the GO website (**http://www.geneontology.org/GO.tools.html**).

6.2. DAG-Edit

DAG-Edit, shown in Figure 1, is a graphical tool developed to browse, query, and edit the GO. It can also be used to create and edit any ontology that has a DAG structure.

DAG-Edit is written in Java, and therefore runs on any platform that supports Java applications; several platform-specific installers are available. A user guide is included in the package and is also available on-line (**http://www.godatabase.org/dev/java/dagedit/docs/index.html**).

A separate package containing a selection of DAG-Edit plug-ins specific for GO, such as tools for managing obsolete terms and for viewing gene product annotations, is available. DAG-Edit is open source and can be downloaded freely (**http://sourceforge.net/project/showfiles.php?group_id=36855**).

6.3. AmiGO

The AmiGO tool (**http://www.godatabase.org/cgi-bin/go.cgi**), shown in Figure 2, provides an HTML interface for querying and browsing the ontologies, term definitions, and associated annotated gene products. AmiGO displays GO terms as an expandable tree view, with a summary view for displaying the list of gene products associated with each term. The results can be filtered by evidence code or by the organization that submitted the association.

Amino acid sequences are available for most gene products, and these can be selected and downloaded from AmiGO as FASTA files. The AmiGO feature GOst,

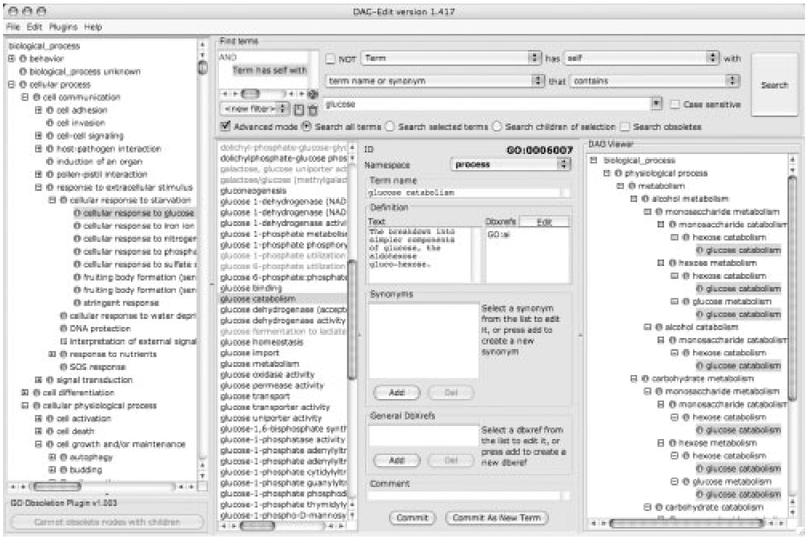

Figure 1 The open source ontology editor DAG-Edit, showing the results of a text search for “glucose”. Tree view, search result, term editing, and DAG view panes are visible

a GO BLAST server, allows users to submit query sequences and retrieve the sequences and GO annotations of all similar gene products in the GO database.

6.4. Documentation

The GO website provides documentation (**http://www.geneontology.org/GO.contents.doc.html**) on all aspects of the project, from the aims and scope of GO to practical advice for curators editing the ontologies or annotating gene products. Links to other resources such as the GO dictionary, GO cross-references, and the GO site at SourceForge are also in this section. GO provides mappings (**http://www.geneontology.org/GO.indices.html**) of its terms to those in other databases to allow preexisting annotations using other classification systems to be “translated” into GO terms. Mappings are maintained to a number of other databases, including the Enzyme Commission (Webb, 1992), MetaCyc (Krieger *et al*., 2004), UniProt Knowledgebase keywords (Apweiler *et al*., 2004), and InterPro entries (Mulder *et al*., 2003).

GO also offers four mailing lists on various aspects of the project, all of which are archived and can be searched. See the Contacting GO web page for details (**http://www.geneontology.org/GO.contacts.html**).

6.5. GO slims

The name “GO slim” refers to condensed versions of the ontologies that consist of a set of high-level GO terms (**ftp://ftp.geneontology.org/pub/go/GO_slims/**). To

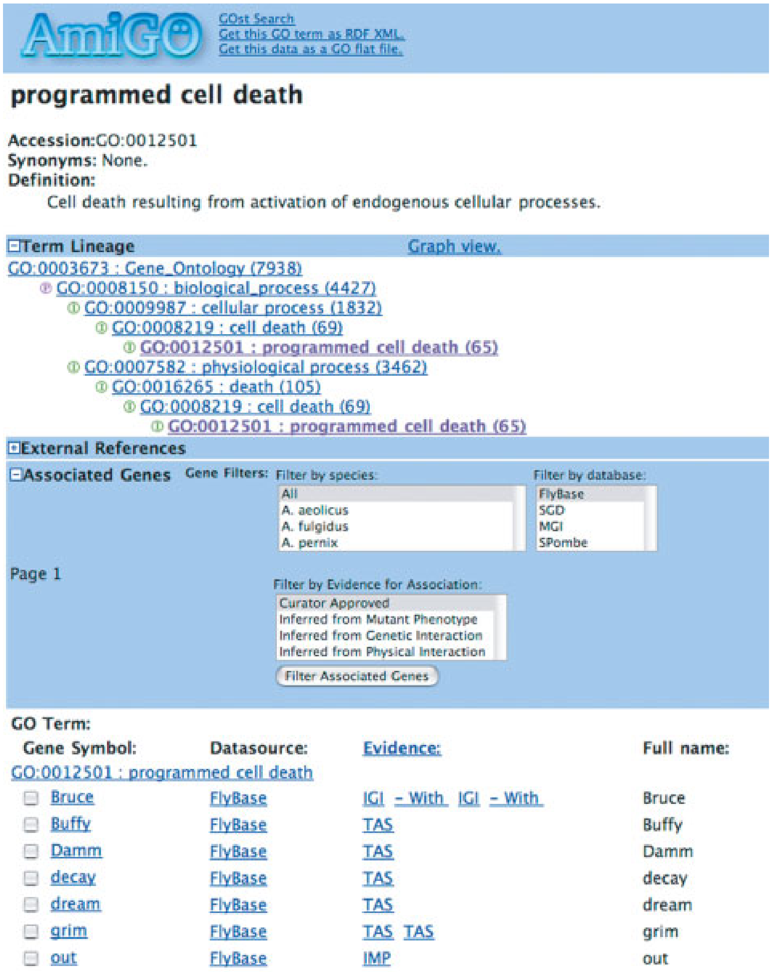

Figure 2 The AmiGO browser (**http: //www.godatabase.org/cgi-bin/go.cgi**), showing details of the GO term "programmed cell death"

gain an overview of the distribution of annotations or just as an introduction to the terms within GO, GO slims are a useful tool. Stored scripts can be used to map a set of GO annotations to the GO slim terms, making comparisons between and within datasets simple. Since GO slims have a number of possible applications, different GO slims have been created using terms relevant to a certain organism or database group. These specific GO slims, along with a generic version, are all stored on the GO web site.

7. OBO

GO is one of the ontologies held in the Open Biological Ontologies (OBO) collection (**http://obo.sourceforge.net/**). By providing controlled vocabularies that

are freely available to be downloaded and used, OBO aims to extend the principles that have guided GO development to cover many additional different biological domains.

There are currently over 40 ontologies lodged in OBO, covering domains such as anatomy, development, and phenotype, genomic, and proteomic information and taxonomic classification. The OBO website provides information on the OBO project in general, a description of each individual ontology, links to related projects, and a mailing list.

8. Conclusion

The Gene Ontology project provides and maintains structured, controlled vocabularies that cover specific domains of biology. An ever-increasing number of model organism and protein databases contribute GO annotations to a central repository. The ontologies and annotation sets are freely available for download from **http://www.geneontology.org/**. The GO web resource, which is continually being updated and expanded, provides documentation about the GO project and links to GO tools.

In the future, the GO project aims to improve consistency, both within the ontologies themselves and within and between gene product annotation sets. GO curators and developers meet regularly to focus on topics such as outstanding issues in representing biological content, or standards for annotations. Data representation improvements and new software features will also help improve the integrity of GO data. The GO Consortium will thus increase the utility of its ontologies even as they become more widely used by the biology, bioinformatics, and computer science communities.

Acknowledgments

This work represents the efforts of all members of the Gene Ontology Consortium. In particular, we thank Dr. Judith Blake for critical reading of the manuscript. The Gene Ontology Consortium is supported by NIH/NHGRI grant HG02273, and by grants from the European Union RTD Programme "Quality of Life and Management of Living Resources" [QLRI-CT-2001-00981 and QLRI-CT-2001-00015].

Specialist Review

Ontologies for information retrieval

William Richard Hersh
Oregon Health & Science University, Portland, OR, USA

1. Definition and overview of IR

To some, the term "information retrieval" may imply the retrieval of all types of information. But for those who work in the field and publish its literature, information retrieval (IR) implies the more focused aspect of document retrieval. However, even those in the field have come to take a broader view of IR with the growth of multimedia content and the World Wide Web. IR applications were among the earliest computer applications, with initial systems available in the 1950s and 1960s. This author has written a textbook on IR from the biomedical perspective (Hersh, 2003).

Nonetheless, IR concerns itself with the indexing and retrieval of information from heterogeneous and mostly textual information resources. The term itself was coined by Mooers in 1951, who advocated that it be applied to the "intellectual aspects" of the description of information and systems for its searching (Mooers, 1951). The advancement of computer technology, however, has altered the nature of IR. As recently as the 1970s, Lancaster (1978) stated that an IR system does not inform the user about a subject; it merely indicates the existence (or nonexistence) and whereabouts of documents related to an information request. At that time, of course, computers had considerably less power and storage than today's personal computers. As a result, systems were sufficient to handle only bibliographic databases, which contained just the title, source, and a few indexing terms for documents. Furthermore, the high cost of computer hardware and telecommunications usually made it prohibitively expensive for end users to directly access such systems, so they had to submit requests that were run in batches and returned hours to days later.

In the twenty-first century, however, the state of computers and IR systems is much different. End-user access to massive amounts of information in databases and on the World Wide Web is routine. Not only can IR databases contain the full text of resources but they may also contain images, sounds, and even video sequences. Indeed, there is continued development of the *digital library*, where books and journals are replaced by powerful file servers that allow high-resolution viewing and printing, and library buildings are augmented by far-reaching computer networks (Lesk, 1997; Arms, 2000; Witten and Bainbridge, 2003).

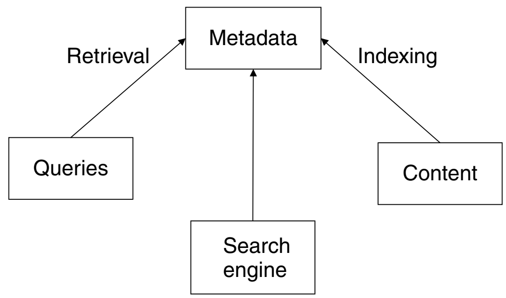

Figure 1 Components of the information retrieval system

One of the early motivations for IR systems was the ability to improve access to information. Noting that the work of early geneticist Gregor Mendel was undiscovered for nearly 30 years, Vannevar Bush started calling in the 1940s for science to create better means of accessing scientific information (Bush, 1967). In current times, there is equal if not more concern with “information overload” and how to find the more pertinent information within “data smog” (Shenk, 1998). However, important information is still missed. For example, a patient who died in a clinical trial in 2000 might have survived if information about the toxicity of the agent being studied from the 1950s (before the advent of MEDLINE) had been more readily accessible (McLellan, 2001). Indeed, a major challenge in IR is helping users find “what they don’t know” (Belkin, 2000).

There are a number of terms commonly used in IR. An *IR system* consists of *content*, computer hardware to store and access that content, and computer software to process user input in order to retrieve it. Collections of content go by a variety of terms, including *database*, *collection*, or – in modern Web parlance – *site*. In conventional database terminology, the items in a database are called *records*. In IR, however, records are also called *documents*, and an IR database may be called a *document database*. In modern parlance, items in a Web-based collection may also be called *pages*, and the collection of pages called a *website*.

A view of the IR system is depicted in Figure 1. The goal of the system is to enable the user to access the content. Content consists of units of information, which may themselves be an article, a section of a book, or a page on a website. Users seek content by the input of queries to the system. Content is retrieved by matching *metadata*, which is meta-information about the information in the content collection, common to the user’s query and the document. Metadata consist of both indexing *terms* and *attributes*. Indexing terms represent the subject of content, that is, what it is about. They vary from words that appear in the document to specialized terms assigned by professional indexers. Indexing attributes can likewise be diverse. They can, for example, consist of information about the type of a document or page (e.g., a journal article reporting a randomized controlled trial) or its source (e.g., citation to its location in a journal and/or its Web page address). A *search engine* is the software application that matches indexing terms and attributes from the query and document to return to the user.

There are two major intellectual or content-related processes in building and accessing IR systems: indexing and retrieval. *Indexing* is the process of assigning metadata to items in the database to facilitate and make their retrieval efficient. The term *indexing language* refers to the sum of possible terms that can be used in the indexing of terms. There may be, and typically are, more than one set of indexing terms, hence indexing languages, for a collection.

In most bibliographic databases, for example, there are usually two indexing procedures and languages. The first indexing procedure is the assignment of indexing terms from a *controlled vocabulary* or *thesaurus* by human indexers. In this case, the indexing language is the controlled vocabulary itself, which contains a list of terms that describe the important concepts in a subject domain. The controlled vocabulary may also contain nonsubject attributes, such as the document publication type. The second indexing procedure is the extraction of all words that occur (as identified by the computer) in the entire database. Although one tends typically not to think of word extraction as indexing, the words in each document can be viewed as descriptors of the document content, and the sum of all words that occur in all the documents is an indexing language.

Retrieval is the process of interaction with the IR system to obtain documents. The user approaches the system with an *information need*. Belkin *et al*. (1978) have described this as an *anomalous state of knowledge* (or ASK). The user (or a specialized intermediary) formulates the information need into a *query*, which most often consists of terms from one or more of the indexing vocabularies, sometimes (if supported by the system) connected by the Boolean operators AND, OR, or NOT. The query may also contain specified metadata attributes. The search engine then matches the query and returns documents or pages to the user.

Researchers in the IR field have a strong history of evaluating their systems using large-scale, widely available test collections, which usually consist of content (documents), statements of information needs (queries), and relevance judgments designating which documents are relevant for given queries. Many researchers participate in the Text Retrieval Conference (TREC, **trec.nist.gov**), an annual forum devoted to system evaluation. TREC is subdivided into various tracks representing common interests of researchers, such as question-answering and document filtering. While most tracks use common newswire and related content, one track that has been recently organized is the Genomics Track (**http://ir.ohsu.edu/genomics/**), which is devoted to evaluating IR systems using genomics documents (Hersh *et al*., 2004).

2. IR ontologies and thesauri

Many who are purists in their definition of ontologies would probably not describe the thesauri used for indexing in IR systems as ontologies. These resources are best described as controlled terminologies that describe the content likely to appear in the database (*see* Article 79, **Introduction to ontologies in biomedicine: from powertools to assistants**, Volume 8 and Article 87, **Merging and comparing ontologies**, Volume 8). However, thesauri serve an important role in indexing

content for retrieval, and they can also be the core of concepts that could be derived to generate a purer ontology.

The purpose of thesauri in IR is to provide a controlled set of terminology that both describes the content and provides concepts for user searching. Indexing of documents long preceded the computer age. The most famous early cataloger of medical documents was John Shaw Billings, who avidly pursued and cataloged medical reference works at the Library of the Surgeon General's Office (Miles, 1982). In 1879, he produced the first index to the medical literature, *Index Medicus*, which classified journal articles by topic. For over a century, *Index Medicus* was the predominant method for accessing the medical literature. By the middle of the twentieth century, the Medical Literature Access and Retrieval System (MEDLARS) was put into place to facilitate the cataloging and indexing of medical literature. This gave rise to MEDLARS on-line, or MEDLINE, the database of literature formerly accessed in *Index Medicus*.

Even though the medium has changed, the human side of indexing the medical literature has not. The main difference in the computer age is that a second type of indexing, automated indexing, has become available. Thus, most modern commercial content is indexed in two ways:

1. Manual indexing – where human indexers, usually using standardized terminology, assign indexing terms and attributes to documents, often following a specific protocol.
2. Automated indexing – where computers make the indexing assignments, usually limited to breaking out each word in the document (or part of the document) as an indexing term. Ongoing research is attempting to identify terms in standardized terminology for automated indexing (*see* Article 86, **Automatic concept identification in biomedical literature**, Volume 8 and Article 84, **Ontologies for natural language processing**, Volume 8)

Manual indexing has mostly been done with bibliographic databases. In the age of proliferating electronic databases, such as on-line textbooks, practice guidelines, and multimedia collections, manual indexing has become either too expensive or outright infeasible for the quantity and diversity of content now available. Thus, there are increasing numbers of databases that are indexed only by automated means.

3. Characteristics of IR ontologies/thesauri

Before discussing specific vocabularies, it is useful to define some terms, since different writers attach different definitions to the various components of thesauri. A *concept* is an idea or object that occurs in the world, such as the condition under which human blood pressure is elevated. A *term* is the actual string of one or more words that represent a concept, such as `Hypertension` or `High Blood Pressure`. One of these string forms is the preferred or *canonical* form, such as `Hypertension` in the present example. When one or more terms can represent a concept, the different terms are called *synonyms*.

A controlled vocabulary usually contains a list of certified terms that are the canonical representations of the concepts. Most thesauri also contain relationships between terms, which typically fall into three categories:

1. Hierarchical – terms that are broader or narrower. The hierarchical organization not only provides an overview of the structure of a thesaurus but can also be used to enhance searching.
2. Synonymous – terms that are synonyms, allowing the indexer or searcher to express a concept in different words.
3. Related – terms that are not synonymous or hierarchical but are somehow otherwise related. These usually remind the searcher of different but related terms that may enhance a search.

4. Medical Subject Headings (MeSH)

The Medical Subject Headings (MeSH) vocabulary was created by the NLM for indexing *Index Medicus*; the MeSH vocabulary was and is now used to index most of the databases produced by the NLM (Coletti and Bleich, 2001). Other systems use MeSH to index their bibliographic content as well, such as the Web catalog CliniWeb (Hersh *et al*., 1996) and National Guidelines Clearinghouse (**www.guideline.gov**). The latest version of MeSH contains over 19 000 *headings* (the word MeSH is used for the canonical representation of its concepts). It also contains over 100 000 supplementary concept records in a separate chemical thesaurus. In addition, MeSH contains the three types of relationships described in the previous section:

1. Hierarchical – MeSH is organized hierarchically into 15 *trees* (see Table 1).
2. Synonymous – MeSH contains a vast number of *entry terms*, which are synonyms of the headings. The majority of these entry terms are “nonprint entry terms”, which are mostly variations of the headings and entry terms in plurality, word order, hyphenation, and apostrophes. There are a smaller number of “print entry terms”, which appear in the printed MeSH catalog. These are often called *see references* because they point the indexer or searcher back to the canonical form of the term.
3. Related – terms that may be useful for searchers to add to their searches when appropriate are suggested for many headings.

The MeSH vocabulary files, their associated data, and their supporting documentation are available on the NLM’s MeSH website (**www.nlm.nih.gov/mesh/**). There is also a browser that facilitates exploration of the vocabulary (**www.nlm.nih.gov/mesh/MBrowser.html**). A paper-based catalog with documentation is available as well (*Medical Subject Headings*, 2005).

Figure 2 shows a partially pruned version of some of the terms in hierarchical proximity to various genes.

There are additional features of MeSH designed to assist indexers in making documents more retrievable (*Features of the MeSH Vocabulary*, 2000). One of these

Table 1 The top-level trees of MeSH

Anatomy [A]
Organisms [B]
Diseases [C]
Chemicals and Drugs [D]
Analytical, Diagnostic and Therapeutic Techniques and Equipment [E]
Psychiatry and Psychology [F]
Biological Sciences [G]
Physical Sciences [H]
Anthropology, Education, Sociology and Social Phenomena [I]
Technology and Food and Beverages [J]
Humanities [K]
Information Science [L]
Persons [M]
Health Care [N]
Geographic Locations [Z]

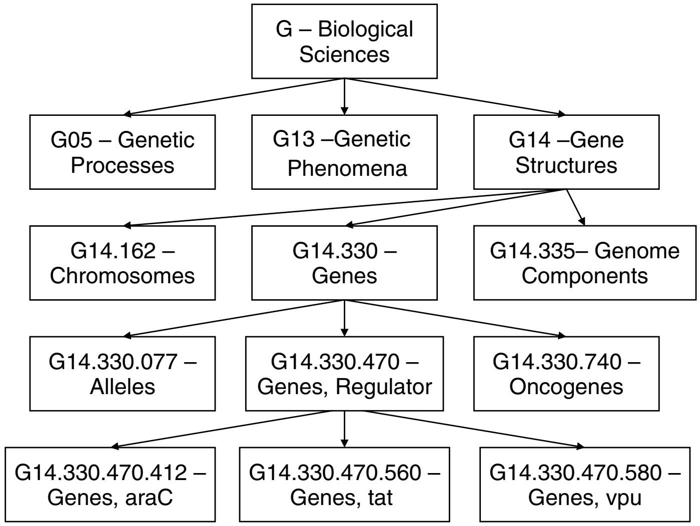

Figure 2 Partially pruned depiction of MeSH hierarchy

is *subheadings*, which are qualifiers to headings that can be attached to narrow the focus of a term. In the `Hypertension`, for example, the focus of an article may be on the diagnosis, epidemiology, or treatment of the condition. Assigning the appropriate subheading will designate the restricted focus of the article, potentially enhancing precision for the searcher. There are also rules for each tree restricting the attachment of certain subheadings. For example, the subheading `drug therapy` cannot be attached to an anatomic site, such as the `femur`.

Another feature of MeSH that helps retrieval is *check tags*. These are MeSH terms that represent certain facets of medical studies, such as age, gender, human or nonhuman, and type of grant support. They are called check tags because the indexer is required to use them when they describe an attribute of the study. For

example, all studies with human subjects must have the check tag `Human` assigned. Related to check tags are the geographical locations in the Z tree. Indexers must also include these, like check tags, since the location of a study (e.g., *Oregon*) must be indicated.

One feature that is gaining increasing importance for clinical searching is the *publication type*, which describes the type of publication or the type of study. A searcher who wants a review of a topic will choose the publication type `Review` or `Review Literature`. Or, to find studies that provide the best evidence for a therapy, the publication type `Meta-Analysis`, `Randomized Controlled Trial`, or `Controlled Clinical Trial` would be used.

While not necessarily being helpful to a searcher using MeSH, the *tree address* is an important component of the MeSH record. The tree address shows the position of a MeSH term relative to others. At each level, a term is given a unique number that becomes part of the tree address. All children terms of a higher level term will have the same tree address up to the address of the parent. It should be noted that a MeSH term can have more than one tree address. `Pneumonia`, for example, is a child term of both `Lung Diseases` (C08.381) and `Respiratory Tract Infections` (C08.730). It thus has two tree addresses, C08.381.677 and C08.730.610.

Another feature of MeSH is *related concepts*. Most well-designed thesauri used for IR have related terms, and MeSH is no exception. Related concepts are grouped into three types. The first is the *see related* references. The MeSH documentation provides examples of how concepts are related (*Features of the MeSH Vocabulary*, 2000). Examples include concepts related between a physiological process and a related disease (e.g., `Blood Pressure` and `Hypertension`) or between a physiological process and a drug acting on it (e.g., `Blood Coagulation` and `Anticoagulants`).

An additional type of related concept is the *consider also* reference, which is usually used for anatomical terms and indicates terms that are related linguistically (e.g., by having a common word stem). For example, the record for the term `Brain` suggests considering terms `Cerebr-` and `Encephal-`. A final category of related concepts consists of main heading/subheading combination notations. In these instances, unallowed heading/subheading combinations are referred to a preferred precoordinated heading. For example, instead of the combination `Accidents/Prevention & Control`, the heading `Accident Prevention` is suggested.

There are two other important features of MeSH terms. The first is the *Annotation*, which provides tips on the use of the term for searchers. For example, under `Congestive Heart Failure`, the searcher is instructed not to confuse the term with `Congestive Cardiomyopathy`, a related but distinctly different clinical syndrome. Likewise, under `Cryptococcus`, the searcher is reminded that this term represents the fungal organism, while the term `Cryptococcosis` should be used to designate diseases caused by Cryptococcus. The second feature is the *Scope Note*, which gives a definition for the term. These can be helpful to the searcher when the use of a term by indexers has changed over time, for example, the term was derived from a broader term used previously or had its name changed at some point in the past.

5. Other ontologies for IR

While MeSH is the most widely used ontology for biomedical IR, it is not the only one used for indexing biomedical documents. Another large biomedical bibliographic database is EMBASE, which is part of *Excerpta Medica*. EMBASE has a vocabulary called EMTREE, which has many features similar to those of MeSH (**www.elsevier.nl/homepage/sah/spd/site/locate_embase.html**). EMTREE is also hierarchically related, with all terms organized under 16 *facets*, which are similar but not identical to MeSH trees. Concepts can also be qualified by *link terms*, which are similar to MeSH subheadings. EMTREE includes synonyms for terms, which include the corresponding MeSH term.

A growing number of resources are linking annotations of gene function in the form of GO codes to the biomedical literature (*see* Article 82, **The Gene Ontology project**, Volume 8). For example, the Mouse Genome Informatics (MGI, **www.informatics.jax.org**) resource links gene names and GO annotations to references in the literature classified by the type of evidence provided (Bult *et al*., 2004). Likewise, the NLM Entrez Gene resource (**http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene**) which catalogs literature, data, and other information about genes, provides GO annotations with linkages to the literature (Maglott *et al*., 2005). Indeed, the growing number of model organism databases and other linked resources will ensure that the ontologies described in other chapters will provide access, even if only directly, to literature and other content present in IR systems.

No discussion of ontologies for biomedical IR would be complete without the mention of the Unified Medical Language System (UMLS) (Humphreys *et al*., 1998; *see also* Article 81, **Unified Medical Language System and associated vocabularies**, Volume 8). Although described in another chapter, this resource is important for IR. The UMLS Metathesaurus provides linkages across different controlled terminologies as well as tools to facilitate the use of IR systems. Indeed, as genome-related discoveries make their way into clinical medicine, the linkage to clinical findings (SNOMED), tests (LOINC), and diagnoses (ICD-9) will become more important.

6. Future directions for ontologies in IR

The growing amount of data from sequencing, microarray, and other experimental modalities provide a case for the use of IR systems. As knowledge is gained and biological processes annotated, the importance of rich ontologies will continue to grow. This situation will motivate both the understanding and improvement of IR systems.

Specialist Review

Ontologies for natural language processing

Yves A. Lussier
Columbia University, New York, NY, USA

1. Introduction

Rapid technological improvements of biomedical computational semantics and natural language processing (NLP) are leading to a profound transformation in the reuse of scientific journal articles in the form of curated and highly computational knowledge stored in specialized biomedical databases, which are proliferating and increasingly structured with ontologies (e.g., Gene Ontology). New computational semantic methods use these ontologies as intermediaries to bridge the gap among research communities and their databases by providing cross-disciplinary and high-throughput results. Moreover, technological standardization of *declarative knowledge*, a highly computable data structure using logic, and communication standards (e.g., XML, RDF, OWL) have profoundly accelerated the development cycles in computational semantics, resulting in ontology-anchored databases that can be automatically transformed. However, scientific biomedical literature remains the pinnacle of knowledge in breadth and depth. Though current generation of *literary knowledge* trumps declarative knowledge in quantity, its noticeable value is compromised at a *retrieval cost*, owing to literary knowledge being buried in an overwhelming growth of scientific articles. Similarly, data entry of biomedical databases derived from scientific journals, generally accomplished via manual annotation, is a rate-limiting and costly process. Automated data structures derived from NLP portend instantaneous and comprehensive *linguistic knowledge* across boundless scientific articles and research communities. However, while linguistic knowledge is computable, it does not allow for the same quality of inference as declarative knowledge. Thus, increasing efforts have been invested to translate linguistic data structures generated by NLP into ontology-anchored declarative data sets to obtain otherwise unattainable large-scale or cross-disciplinary inferences. As the gap between linguistic and declarative knowledge is bridged, we are witnessing a paradigm shift. Biomedical knowledge amassed in unprecedented volume is likely to enable large-scale computational analysis that, in turn, could facilitate reductionist and synthetic hypotheses.

Our working definition of the term “ontology” will encompass formal logical terminological systems of logic erected on axioms (Sowa, 2000) with terminologies

based on semiexplicit subsumptions from which inferences can be derived (Guarino, 1998).

This article focuses on the convergence of biomedical ontologies, originally developed to structure databases, and linguistic data structures produced by NLP operating on unstructured or semistructured corpora. Theories upon which the convergence of NLP, biomedical informatics and ontologies are being conducted will first be addressed in Section 1, followed by a description of the properties of ontologies that make them suitable for NLP in Section 3. Section 4 will follow with concrete examples of ontologies addressing representation of biological knowledge and a succinct analysis of their readiness for use by NLP systems. Section 5 will provide examples of NLP systems mapping to ontologies. In conclusion, Section 6 will summarize past accomplishments and their limitations, and point out future directions.

2. Theoretical background

As biomedical ontologies, NLP systems and computational semantics converge, their respective theories and principles are bound to challenge or enrich one another. As described elsewhere, Aristotle's theories of syllogism, knowledge representation and first-order description logic are widely used in the field of computational semantics (Sowa, 2000). Here, we will discuss three additional contemporary theories, which are germane to the use of ontologies for NLP in biomedicine: (1) Ogden and Richards' semiotic triangle; (2) Marsden Blois' conjecture on information in biomedicine; and (3) the sublanguage theories of Zellig Harris.

2.1. Ogden-Richards' semiotic triangle

As shown in the bottom of Figure 1, a subject matter of an investigation or science (object) can be represented by a symbol or *term*; a term is a text string consisting of one or many words that together have a precise meaning. This theory provides a basis for defining symbol *ambiguity* and *redundancy*, which respectively refer to the clashing of related concepts sharing similar symbols superficially confounded as being the same object, and to unique objects having distinct and apparently unrelated symbol representations, leading to duplication of the concept in the metathesauri. While these principles are suitable for domains of science where relevant knowledge is relatively stable over time, they are sometimes oversimplified for representing the rapid evolving field of biomedicine, in which many discoveries are cross-disciplinary and likely to extend or modify the meaning of some terms. Concurrently, there has been a growth of specialized biomedical ontologies and metathesauri of ontologies, such as the Unified Medial Language System (UMLS) (Lindberg, 1990) or the National Cancer Institute (NCI) Metathesaurus (Covitz *et al*., 2003), that are aimed at bridging the gap between different standards. The proposed approach of systematically analyzing the three semiotic facets, "symbol, object, and concept", provided a model-theoretic foundation for evaluating metathesauri (Campbell *et al*., 1998) that could also be used to evaluate the

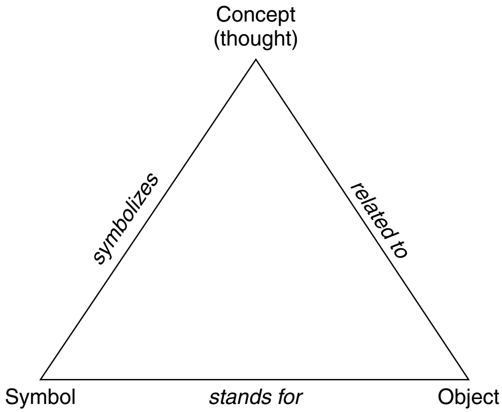

Figure 1 The adapted Ogden and Richards semiotic triangle

meanings of linguistic-semantic data structures composed by an NLP system where the original narrative is considered as the object or its proxy (Figure 1).

2.2. *Marsden Blois' conjectures on information in biomedicine*

Blois (1984) proposed a visionary conjecture of biomedical information processing derived from the Hartley-Shannon-Weaver view of information. He hypothesized that structures, functions, and processes observed at different scales of biology could be represented and assembled in a formal system by following a few simple rules. (1) At any given "descriptive level" (scale of biology), a "nominal" structure, function, or process can be described as a function of "attributes". (2) These nominals cannot be attributes at the same descriptive level. (3) Moving toward the macroscopic level, nominals at one descriptive level respectively become attributes, while attributes of a previous level eventually disappear and become "embedded" in nominals and attributes of higher levels. (4) "Emerging attributes come into existence with each increased level" and contribute to the behavior of nominals in all levels above. (5) Moving up the descriptive levels, nominals and attributes which are assumed to have crisp and unambiguous definitions (e.g., nucleotide sequences, etc.) and behaviors at molecular levels become increasingly fuzzy to describe and "particular" (used by Blois to address somewhat dissimilar phenotypes from one organism to another), thus giving rise to the complexity of presentation of nonmolecular phenotypes, diseases, and individuality. While some have rightly argued that this theory requires confirmation with falsifiable hypotheses, it is generally regarded as providing a foundation for the development of second-generation knowledge-based systems and reusable domain ontologies in biomedicine (Musen, 2002; Rector *et al*., 2002). Besides ontologies, Blois' theory can help postulate hypotheses on current manually annotated biological databases that span different scales of biology such as the molecular networks of genes and gene products. Indeed, Blois' theory is implicitly or explicitly used in biomedical object-oriented software and databases erected on foundational ontologies (e.g.,

KEGG; *see* Article 101, **Design of KEGG and GO**, Volume 8) and the model organism database systems (e.g., Flybase – Ashburner *et al*., 1994, etc.). In summary, Blois' theory has been pivotal in improving ontologies and is likely to play a role in conceiving NLP systems capable of reusing, improving, or coding in these ontologies.

2.3. *Zellig Harris sublanguage theory*

In 1968, Harris observed that the grammar of a sublanguage is quite different from that of standard language. For example, well-formed patient histories in medicine are written telegraphically, omitting verbs and articles. Harris proceeded to hypothesize that scientific subspecialties use specialized sublanguages, which can be represented as information content and structure. The grammar of a sublanguage can be determined by observing its combination of elements. Harris' theory has become well established as it has been comprehensively evaluated and corroborated. Friedman provides an overview of the theory with examples in biology and medicine (Harris, 2002; Friedman *et al*., 1995). Fundamentally, Harris' theory has helped determine a number of semantic properties that result in additional restrictions on linguistic structure. Thus, accurate NLP systems based on this theory have been shown to provide semantically rich data structures that can be straightforwardly associated with ontologies and predicate logic (Hripcsak *et al*., 1995; Friedman *et al*., 2001; Rzhetsky *et al*., 2004).

3. Properties of ontologies

In this section, we will describe the properties of ontologies, which may contribute to discerning their usefulness for NLP. In Section 3.1, we will address the scale of biology covered by contemporary ontologies, followed by criteria for ontological control (Section 3.2), relationships (Section 3.3), and suitability for NLP (Section 3.4).

3.1. *Scales of biology and of phenotypes*

The dogma of molecular biology postulates that three distinct components, genes, phenotypes, and environment, intervene in the development and function of an organism. Table 1 analyzes the content coverage of several ontological tools according to the conceptualization of different structure and attribute scales, such as size (meter), weight (kilogram), and scientific field. A recently published review of biomedical ontologies provides an in-depth analysis of their design (Bard *et al*., 2004). Owing to the wide span of phenotypic information and the large number of related ontologies, we will focus this section on the heterogeneous "conceptual" properties of phenotypes.

As described in Blois' theory, genes and gene products generally have a "crisp" definition owing to their quantized physical nature. In contrast, nonmolecular

phenotypes possess fuzzy physical boundaries that are highly compositional in nature (Rector *et al*., 2002; Elkin *et al*., 1998a,b Mays *et al*., 1996; Stuart *et al*., 1995). For example, one can refine a phenotypic description with additional modifiers as shown below in pseudocode:

```
[ {Abnormal Anatomy: "right humeral fracture"}]≡
    [{Regional Anatomy: Laterality: "right"}
    {Systemic Anatomy: Bone: "humerus"}
    {Abnormal Anatomical Structure: Morphology: "fracture"} ]
```

When components of a composite phenotypic concept are implemented in a database schema, instead of the terminology model, related implicit knowledge may be buried in the software architectures. Some ontologies propose a postcoordination strategy analogous to the schema of the databases they serve. In such architectures, both meta-data and terminological information are required to reconstruct a complete composite concept. For example, one ontology could represent separately the anatomy and the morphology of the previous example, while another ontology could represent them as a single composite concept. In addition, differences in *granularity of conceptual* representations are variant representations of the same phenotypic concept in an ontology focusing on the class concept, where in an ontology capturing their specific nuances they would be considered distinct phenotypes. Highly granular ontologies (nomenclature-like) maximize the content of necessary concepts and minimize the contingent ones, but it is difficult to define crisp criteria to distinguish ambiguous cases. While ontological data structures are challenged by the compositionality, granularity, and expressiveness of phenotypes, this is not necessarily the case of linguistic data structures, which may support nested and recursive relationships.

3.2. Principles of controlled terminology applied to ontologies

The terms of ontologies, not their relationships, can be considered a subset of controlled terminologies. In Table 2, we have adapted established desiderata for controlled terminologies (Cimino, 1998) to characterize the contemporary ontologies. The “ontological control” subclasses are defined as follows:

- *Concept-oriented*: unit of symbolic processing is the concept.
- *Formal semantic definition of concepts*: use formal descriptive language incorporating other concepts within the definition.
- *Concept permanence*: meaning of a concept should not change over time and the representative symbol should not be deleted from the ontology, simply “retired” if need be.
- *Nonredundancy*: definition of a concept should be unique and explicit.
- *Nonambiguity*: distinct concepts should not share the same term or synonym unless explicitly stated.

Table 2 Properties of biomedical ontologies including suitability for NLP thesauri

[a]McCray (1994) Lexical methods for managing variation in biomedical terminologies. Proceedings of the 18th Annual Symposium on Computer Applications in Medical Care, 235–239

- *Nonsemantic concept identifier*: codes representing concepts should be meaningless (not representative of relationships to other concepts), as concepts are sometimes relocated in hierarchies, and it has been shown that most semantic identifiers become a barrier to concept permanence.

3.3. Relationships

Relationships between concepts differentiate the expressiveness of ontologies. For example, property-derived ontologies usually only maintain subsumption types of relationships ("is a" or "part of"). The subclasses are defined as follows:

- *Monohierarchy (tree)*: each concept has only one parent, which is critical for current phylogenetic analyses.
- *Polyhierarchy*: concepts may have more than one parent, which is useful for complex phenotypesthat can be classified in many complementary, yet distinct, ways.
- *Directed Acyclic Graph* (*DAG*): no cycles are created in the semantic network of relationships.
- *Internal semantic relationships*, in addition to subsumption.
- *Semantic relations to external ontologies*: some new ontologies point to external ontologies using a semantic relationship to generate a transontology network (e.g., translation tables).

3.4. Suitability criteria for NLP

The "NLP Suitability" subclasses that provide criteria to discriminate among the values of distinct terminologies are defined as:

- *Semantic Disambiguation of Synonyms*: Though controlled terminologies used for database queries should be unambiguous, those used for NLP need to reflect their original knowledge sources. While merging different ontologies from cross-disciplinary domains, it is not unusual to have terminological overlaps. By design, some ontologies make such overlaps explicit by leaving existing relationships in the source terminologies unchanged. Such explicit semantic disambiguation of synonyms may provide clues on contextual usage and be advantageous to the NLP community.
- *Abbreviations/Symbols*: must be recognized for the disambiguation of narratives.
- *Historical usage of concepts/terms/relationships*.
- *Lexical Variants*.
- *Lexicon-Adapted NLP*.
- *Lexical Software*.
- *Terminology Server*: reduces the total cost of operation of a distributed component-based system.
- *Proof-of-Concept*: ontology has been proven to work with an NLP system.

4. Biomedical ontologies for NLP

Biomedical ontologies are constrained data structures favoring computations with formal hierarchies and semantics. Formal ontologies and their associated systems (Musen *et al*., 1995; Rector *et al*., 1997, 1998; Campbell *et al*., 1994) are robust architectures designed for knowledge representation of concepts in a formal language (e.g., predicate logic) and have been used in biology and medicine (Rubin *et al*., 2002; Embley *et al*., 1998; Snoussi *et al*., 2001; Silvescu *et al*., 2001; Friedman *et al*., 1995). Obstacles in modeling knowledge in a formal ontology involve the difficulties and costs of (1) achieving consensus regarding the definition of knowledge representations and (2) enumerating the *context features* and the background knowledge required to ascribe meaning to a specific representation (Musen, 1992; Rector *et al*., 2002; Pole *et al*., 1996). In addition, ontological systems are not designed to operate over semistructured narratives that are not formally represented.

Biomedical ontologies, such as those presented in Tables 1 and 2, differ significantly in their focus (e.g., number of biological scales), granularity (e.g., classifications or nomenclatures), and formalisms of representation. In order to summarize their capabilities for NLP, we have organized them in three categories: (4.1) focused and full-depth ontologies, (4.2) focused classifications, and (4.3) broad-scope and full-depth ontologies.

4.1. Focused and full-depth ontologies

Gene Ontology (GO), Gene Nomenclature (GN), the Universal Virus Database (ICTVdb),National Center for Biotechnology Information NCBI Taxonomy (Taxon) and Cell Ontology (CO) are examples of tightly focused ontologies that have narrow breadth, full depth, and share a number of properties (Table 1). In addition, all these ontologies share a strong formalism of representation distinguishing them from data dictionaries (Table 2). However, with the exception of GN, they do not provide features to accelerate their reuse by an NLP system.

Since the inception of GO in 2000, over 25 distinct model organism database groups and other phenotypic databases have been manually annotated, totaling over five million distinct genes and proteins with a relationship to one of the ten thousand distinct GO concepts (The Gene Ontology Consortium, 2004). This fundamental work has set the stage for increasing the productivity of phenotypic research across different communities using genome-wide integrative discovery tools (Jenssen *et al*., 2001; Perez-Iratxeta *et al*., 2002; Raychaudhuri *et al*., 2003, 2002; Sarkar *et al*., 2003; Jensen *et al*., 2003; McCray *et al*., 2002; Tulipano *et al*., 2003; Bodenreider *et al*., 2002).

4.2. Focused classifications

Various versions of the International Classification of Diseases (ICD-9, ICD-10, and ICD9-CM) are focused *terminologies* that are implicitly constructed, but are not as

straightforward to use as the other ontologies. For example, during annual updates, ICD-9-CM allows unique non-concept-oriented identifiers to be reused for diseases. While these classifications satisfy the previously described ontology definitions, they are generally considered significantly less formal than the other classes. Although methods to circumvent these limitations and use these terminologies as ontologies have been proposed by Cimino (Cimino, 1998), none achieve the depth and scope of the Systemized Nomenclature of Medicine (SNOMED), the UMLS, or the NCI Metathesaurus in the diseases area, and, thus, are probably not the appropriate terminology choices for NLP.

4.3. Broad-scope and full-depth ontologies

These are definitively the most readily available for NLP. SNOMED Clinical Terms (CT), developed and maintained by the College of American Pathologists, provides a broad coverage of clinical and medical concepts. Recently, the content has been significantly increased by merging with the READ codes, used extensively in UK clinical practices. In contrast, the UMLS is a "pure metathesaurus". Since it integrates, using a full graph with cycles, versions of GO, NCBI Taxonomy, ICD-9 CM SNOMED, and Medical Subject Headings (MeSH), the UMLS offers broader breadth and depth than all other ontologies, with the exception of the NCI Metathesaurus. However, it does not offer the most recent translations to its source terminologies since the update process is semiautomated and rate-limiting. Nevertheless, emerging new properties offered by the UMLS, composed of derivative databases and a software toolbox specialized for NLP, make it by far the most adapted terminology for immediate use in NLP (McCray *et al*., 2001; Johnson, 1999; Browne *et al*., 2003).

The NCI Metathesaurus is a hybrid ontology, and likely the largest biomedical ontology available, containing additional source contents and external ontologies. The software services offered by the NCI Center for Bioinformatics (NCICB) are distinct from those of the UMLS, offering direct high-throughput access to their Metathesaurus via the internet and a molecular bioinformatics toolbox called caBIO (Covitz *et al*., 2003). In partnership with the research community, the NCI is creating a common and extensible bioinformatics platform that integrates diverse data types and supports interoperable tools (Cancer Biomedical Informatics Grid - caBIG **http://cabig.nci.nih.gov**).

5. NLP and ontologies

NLP produces data structures that are significantly more flexible than ontologies, but come for a cost. Their linguistic structures, which can be nested and compositional, are more expressive and complicated to analyze than those of ontologies, and the semantic networks produced by NLP systems often comprise cycles that make the reuse of the information challenging and often problematic. A number of approaches have been used to determine the usage of ontologies for NLP. Proof-of-concept projects demonstrated that, though the knowledge found in narratives is

highly nested and densely embedded, an NLP system based on sublanguage grammar can be coordinated with a large scale ontology for coding purposes (Friedman *et al*., 2004; Lussier *et al*., 2001). Other studies aimed at understanding the ambiguity sources of combined ontologies, showed them to be both internal and external ambiguity (Tuason *et al*., 2004). Additionally, the semantic context afforded by some ontologies has been shown to be useful for NLP (Rindflesch *et al*., 2003), extending its accuracy and expressiveness (Baclawski *et al*., 2000). Other NLP researchers have conceived their systems, relying intensively on a body of domain knowledge derived from the conceptual formalism of ontologies, and common methodological and theoretical principles to enforce this convergence (Zweigenbaum *et al*., 1995; Friedman *et al*., 2001). As shown in Table 1, under "NLP Content Coverage", while contemporary NLP systems provide adequate coverage of the gene and gene product (Friedman *et al*., 2001), and clinical scales (Sager *et al*., 1995; Friedman *et al*., 1997; Zweigenbaum *et al*., 1997, 1998; Wagner *et al*., 1998; Lovis *et al*., 1998; Rassinoux *et al*., 1997), the cellular and subcellular levels are inadequately represented. Significantly, an NLP method coding narratives in Gene Ontology has also been developed (Raychaudhuri *et al*., 2002). The National Library of Medicine (NLM) provides the most comprehensive services and products designed to facilitate the integration of and focus scientific research at the intersection of NLP and ontologies, such as: (1) the UMLS database, comprising a semantic network connecting several ontologies and providing a comparative analysis of term ambiguity, (2) the "Specialist Lexicon", designed specifically for NLP technology, (3) an open-source computational toolbox for reuse of the lexical and ontological UMLS databases, and (4) Lexical Properties of GO (McCray *et al*., 2002).

6. Conclusions and future directions

Three contemporary theories providing the framework for the integration of their respective fields were covered: semantics (Semiotic Triangle), informatics (Information Flow in Scales of Biomedicine), and NLP (Sublanguage Theory). In addition, the potential of ontologies covering a large variety of genotypic and phenotypic information in biomedical knowledge representation have also been described. Metathesauri, such as the UMLS and NCI Metathesaurus, combine the best ontologies in an increasingly computable form, as well as providing lexicon and open-source software specialized for NLP, flexible linguistic models of language and formal ontological models of concepts. However, at least two important domains are not well covered by classification terminologies: (1) strains of viruses, bacteria, fungi, and cell lines, and (2) environmental factors from experimental designs and conditions.

While reusing ontologies as lexicons for NLP systems is reasonably straightforward, coding narratives in a formal ontology remains challenging. In practice, coding genes from narratives remains difficult for NLP due to ambiguities in the English language, as well as the problems related to expressiveness, compositionality, and granularity. In order to query or infer using such large-scale knowledge, one has to simplify the nested or complicated forms to a standardized format via inefficient and rate-limiting transformations. However, recent studies have identified

methods to incrementally annotate narratives in XML format, first with linguistic constructs and second with declarative constructs (Friedman *et al*., 1999). In such form, data (narratives), information (linguistic structures), and knowledge (declarative structures, ontological coding) coexist, and queries can be conducted efficiently. Lexicons of NLP techniques have been enriched with ontological terms to produce coded output, but the fundamental problem of expressiveness remains: data structures produced by an NLP system are more informative than ontologies, while the latter are currently more computable. By extension of the Harris Sublanguage Theory, linguistic systems may eventually augment or even challenge the current curation of ontologies with automated and dynamic annotation of biomedical ontologies driven by the corpora of the scientific communications (Mollah *et al*., 2003; Campbell *et al*., 2002).

In conclusion, hybrid technologies using ontologies and NLP are poised to produce a paradigm shift in the annotations of biological databases, currently accomplished manually.

Specialist Review

TAMBIS: transparent access to multiple bioinformatics services

Robert Stevens, Norman W. Paton, Sean Bechhofer, Gary Ng, Martin Peim, Patricia Baker, Carole Goble and Andy Brass
University of Manchester, Manchester, UK

1. Introduction

In this article, we describe Transparent Access to Multiple Bioinformatics Information Sources (TAMBIS) (Goble *et al.*, 2001), an ontological approach to solve a perennial problem in bioinformatics – that of integrating or interoperating between multiple diverse bioinformatics data and analytical resources (Karp, 1995). Bioinformatics resources present a classic example of autonomous and heterogeneous resources that need to be integrated to accomplish many bioinformatics analyses. For instance, a bioinformatician may select a sequence from swiss-prot, perform a similarity search with BLAST, and then perform a search against PROSITE with each of the resulting top hits from the similarity search. As well as the biological question prompting this analysis, the bioinformatician needs to know:

- the resources to be used in the analysis;
- where those resources are located (usually on the Web);
- in which order to use those resources;
- how to use the individual resources; and
- how to transfer data between those resources.

All of these requirements place a large burden of knowledge on a bioinformatician or biologist. The last point, in particular, is the crux of the computational problem in the integration of multiple bioinformatics information sources (Karp, 1995; Davidson *et al.*, 1995). The reality of integrating these resources is that they were rarely designed to be used together and that constructing requests that refer to several resources is time consuming and error-prone.

This scenario makes work in such an area a central topic in bioinformatics. The aim is to let a biologist ask the biology question and have the application deal with the mechanics of how to answer that question. There is a general need to *integrate* bioinformatics resources – that is, make these diverse resources work together

(Karp, 1995). Thus, within bioinformatics, there is a need to create suitable query-building facilities over diverse, heterogeneous, and distributed resources as well as suitable middleware technology for answering such questions (Davidson *et al*., 1995). In essence, there is a need to capture the knowledge of how to perform a task within bioinformatics software and to enable a scientist to use his or her domain knowledge to pose the question.

The difficulty in integrating these diverse resources to enable common queries are the differences or heterogeneities between those resources. These heterogeneities exist at two levels in bioinformatics resources – first, at the syntactic or structural level; and second, at the semantic level. Databases and services operate with different communication protocols and through applications running on different platforms, and yield results in many proprietary formats. All of these points and more make even simple integration between resources difficult because of syntactic heterogeneity. On top of this problem is that of the concepts within bioinformatics being represented differently in many resources. The same concept can have different representations and different concepts can have the same representation. This heterogeneity can exist both at the schema level and at the level of the values held within a schema (Karp, 1995). This semantic heterogeneity makes asking questions over multiple resources difficult, as the user or the query machinery needs to accommodate the differing representations of biological knowledge within diverse resources.

A biologist should be free to ask the biological questions he or she wishes to ask – without necessarily having to know the answers to all those points listed above. Our proposal in TAMBIS was to make all these issues *transparent* to a biologist by holding that knowledge within the query application in the form of an ontology (*see* Article 79, **Introduction to ontologies in biomedicine: from powertools to assistants**, Volume 8 and Article 80, **Ontologies for the life sciences**, Volume 8) (Goble *et al*., 2001). This *transparency* gives the name to the project: Transparent Access to Multiple Bioinformatics Information Sources (TAMBIS) (**http://img.cs.man.ac.uk/tambis**).

2. Integrating bioinformatics resources

In general, the strategy in overcoming syntactic heterogeneity is to provide a middleware layer into which heterogeneous resources can be *included* and *transformed* to provide a common programming or querying interface for an application. BioKleisli, later to become K1 (Davidson *et al*., 2001), is a middleware layer, data exchange format, and query language directed toward the bioinformatics domain. It includes a wrapping facility that *includes* third-party resources into the middleware layer, and the Collection Programming Language (CPL) allows these wrapped resources to be further *transformed* to provide a set of query facilities of the same syntactic nature over these wrapped resources. In BioKleisli, the declarative, composition-based CPL is provided to orchestrate multiple resources via their wrappers and collect results. Figure 1 shows the CPL for a typical multi source bioinformatics query. In the BioKleisli system, the joining of resources is delegated

```
{m |
\p <getspentrybyspecies("guppy"),
\p2 <doblastpsearchonspentry(p),
\m <doprositescanonspentry(p1)};
```

Figure 1 CPL expression for the query "Find all the motifs on all proteins that are significantly similar to any guppy protein"

to the middleware, but the user still has to manage the semantic heterogeneity (e.g., which resource to use and in which order to use those resources).

There are several integration efforts within the bioinformatics arena, but none of them afford the level of transparency needed by some non expert bioinformaticians. The most successful and widely used is the Sequence Retrieval System (SRS) (Etzold *et al*., 1996). SRS has a language for describing, parsing, and indexing flatfile databanks. Combined with a query language and a Web interface, users are able to both formulate queries and query by navigation. The user is, however, still presented with the files with their original semantics; the user has to perform any semantic reconciliation required. For an integration solution, middleware such as BioKleisli is essential, but that only provides a syntactic or structural integration, as seen in SRS. Much of the knowledge burden still lies on the biologist user.

Conforming to a common terminology or ontology can remove these remaining knowledge burdens. By committing to a common terminology or controlled vocabulary that captures knowledge about the domain, a homogenizing layer, acting as a global schema over the autonomous, distributed and heterogeneous bioinformatics resources, can be made. The difficulty is to then map from this global schema, against which queries can be made, down to the underlying resources. That is, there is a need to *mediate* between the global schema and the underlying resources (Wiederhold, 1992). In TAMBIS, we use an ontology to provide this global view or schema over the various bioinformatics resources. This ontology, together with a query processor, provides the mediation between the ontology and the underlying resources.

3. TAMBIS architecture

The following are the kinds of queries that TAMBIS can answer.

- Find any motif indicating a receptor function found on a protein similar to any nucleic acid sequenced for the aardvark.
- Find DNA-binding motifs from eukaryotic proteins involved in apoptosis.
- Find chimpanzee homologs of human proteins containing seven-bladed propeller domains.
- Find homologs to apoptosis-receptor proteins that also have ATPase activity.
- Find motifs in enzymes using thymine as a substrate and iron as a cofactor.

All such queries are complex and multisource. To ask a question such as "Find all antigenic human apoptosis receptor protein homologs and their phosphorylation

site motifs", TAMBIS uses the three sources swiss-prot, BLAST, and PROSITE. In TAMBIS, the user does not have to choose the sources or the keywords with which to filter the proteins or perform any filtering, transformation, or mapping; all these tasks are transparent to the user. The knowledge of how to accomplish these tasks is captured in the TAMBIS ontology and the rest of the TAMBIS application.

Figure 2 shows the architecture of TAMBIS. The geneticXchange middleware layer, K1 or discoveryHub, can be seen at the base of the system; it provides a Java API by which queries formulated in discoveryHub's query language, CPL, (Davidson *et al*., 2001) are passed to and executed against the wrappers. The bioservices currently wrapped within TAMBIS are swiss-prot, ENZYME, BLAST, PROSITE, and CATH. This layer of TAMBIS is the part that actually answers the queries posed by biologists.

The rest of the system is concerned with formulating conceptual, declarative queries; mapping query elements to sources and values used within sources; optimizing the order of calls to methods on the wrapped sources; and finally encoding the query in discoveryHub's query language.

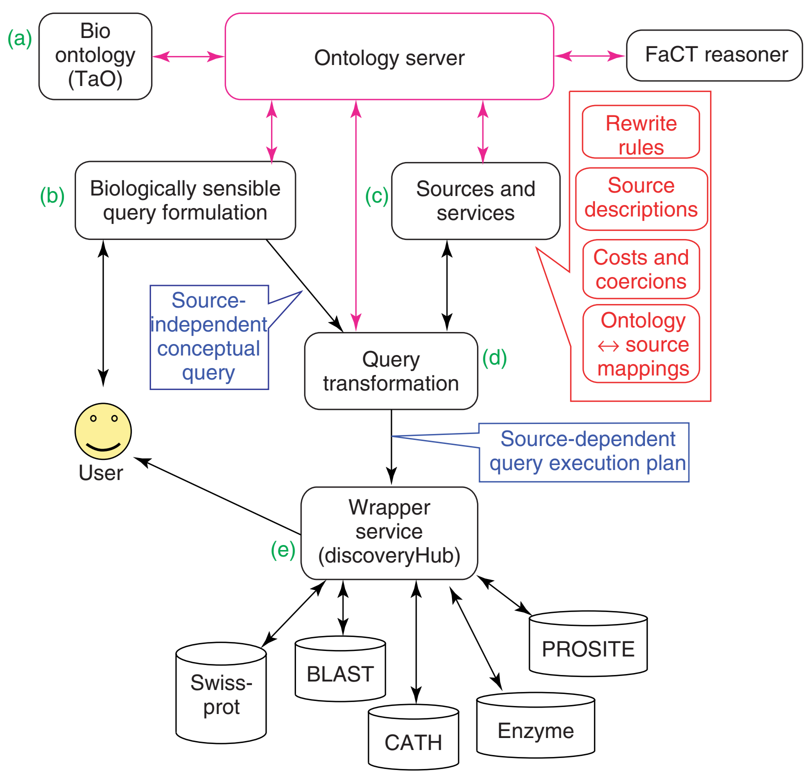

Figure 2 The TAMBIS architecture: (a) The TaO, an ontology of biological and bioinformatics terms; (b) A knowledge-driven query-formulation interface; (c) A services model linking the TaO with the source services; (d) Transformation from high-level, source-independent queries into source-dependent, ordered queries; (e) A wrapper service dealing with external sources provided by discoveryHub

3.1. The TAMBIS ontology

The TAMBIS ontology (TaO) captures knowledge about molecular biology and bioinformatics. Thus, in one ontology, we describe the major entities and relationships within the resources over which we wish to be able to form queries. Table 1 describes the major categories of classes within the TaO, together with examples of the more specialized classes.

As well as the "is a" relationship, these concepts are linked by many other kinds of relationships that describe the biological and bioinformatics domain. These include, but are not limited to, *hasFunction, functionsInProcess, hasAccessionNumber, hasSequence*, and *hasComponent*.

The TaO is encoded in a Description Logic (DL) called GRAIL (Rector *et al*., 1997; *see also* Article 92, **Description logics: OWL and DAML + OIL**, Volume 8). The TaO makes use of the compositional approach to describing concepts that is possible in DLs. For example, `Enzyme` was not simply asserted to exist as a child of `Protein`. `Enzyme` was described (in a logical form) to be a kind of `Protein` that *catalyzes* a `Reaction`. This description "defines" what it is to be an enzyme (*see* Article 92, **Description logics: OWL and DAML + OIL**, Volume 8), and the DL reasoner is able to take such descriptions and infer a subsumption (or "is a" lattice), as well as check for logical consistency within those descriptions (*see* Article 92, **Description logics: OWL and DAML + OIL**, Volume 8).

The TaO acts as a global schema, so users need to be able to form queries against that schema. TAMBIS takes advantage of the DL's dynamic ability to compose queries while the application using the ontology is running. The query-formulation interface (*see* Section 3.2) allows users to build new concepts that act as queries. Thus, the TaO only describes the potential queries a user may make against the resources – the ontology is dynamic and a user can build new queries in the same manner as the concept Enzyme was built.

It is not, however, sensible to be able to compose queries out of concepts without restriction. Naturally, the relationships existing within the ontology provide some restriction, but still some combinations would be biologically nonsensical. Take, for instance, the TaO description `bioMolecule` *hasComponent* `Motif`. In general this is true, but the concept of motif subsumes those that are parts of `Protein` and those that are parts of `NucleicAcid`. The TaO needs a further level of restriction

Table 1 The *domain-general* concepts, which describe the range of concepts covered in the TaO, and *domain-specific* concepts, which describe the depth of coverage within the TaO

General biology	Specific biology
BioMolecule	Protein, enzyme, nucleic acid, DNA, RNA
SequenceComponent	Motif, active site, modification site, amidation site, alpha-helix
BiologicalFunction	Enzyme function, motor activity, hormone function
BiologicalProcess	Cellular process, apoptosis, lactation
CellularComponent	Organelle, chloroplast, ribosome, nucleus, mitochondrion
Species	Eukaryote, yeast, human, aardvark
ProteinStructure	Mainly alpha, mainly beta, seven-bladed propeller, TIM barrel

limiting the general case of `BioMolecule` *hasComponent* `Motif` to be also true at the specific case, for example, of `AlphaHelix` being part of `Protein`. Thus, the TaO contains another level of restriction on the existence of relationships called sanctioning (Rector *et al*., 1997; Baker *et al*., 1999). This sanctioning layer only allows biologically sensible concept compositions to take place and helps guide the user in formulating queries. Such sanctioning is also a form of knowledge about the domain captured by the TaO.

So, we have a mechanism, via the TaO, that offers the chance to form concepts dynamically that describe the instances a biologist wishes to retrieve from bioinformatics resources. The TaO contains knowledge of what can be asked of these resources, but to offer these facilities to biologists, we need to be able to:

1. present a query-formulation user interface;
2. take the conceptual descriptions of instances and transform them to a concrete query plan against the real resources; and
3. execute that query plan against those resources.

The role of the TaO in the TAMBIS architecture is shown in Figure 2. The TaO is made accessible to the rest of the TAMBIS application via a terminology server (TeS). The TeS API allows the TAMBIS client to present a query formulation interface to a biologist. This client can ask questions of the TaO such as "What are the parents/children of concept x?"; "What are the other relationships held by concept x?"; "Is concept x satisfiable, and where does it lie in the lattice?"; and "What relationships are sanctioned for this concept?". Through these questions, the TAMBIS application can use the knowledge within the TaO to promote transparency in the process of building and executing bioinformatics queries.

3.2. The TAMBIS user interface

Figure 3 shows the TAMBIS query-formulation interface. The TaO is used to generate the content of the screen in both the query-formulation interface and an ontology browser. A concept is a query and, in TAMBIS, a user builds a new concept that describes what is to be retrieved. In query formulation, a TaO concept is presented as a button upon the user interface. Clicking the button yields a menu describing what actions may be performed with that concept in building a new concept or query. For instance, the user is offered the relationships to other concepts held by the concept in question. The user may accept a relationship to another concept and thus form a new concept in the TaO. This new concept is progressively refined until the user has described what instances he or she wishes to retrieve.

3.3. The TAMBIS query processor

The Sources and Services Model (SSM) (Figure 2) provides metadata describing the relationship between the resource-independent knowledge captured in the TaO

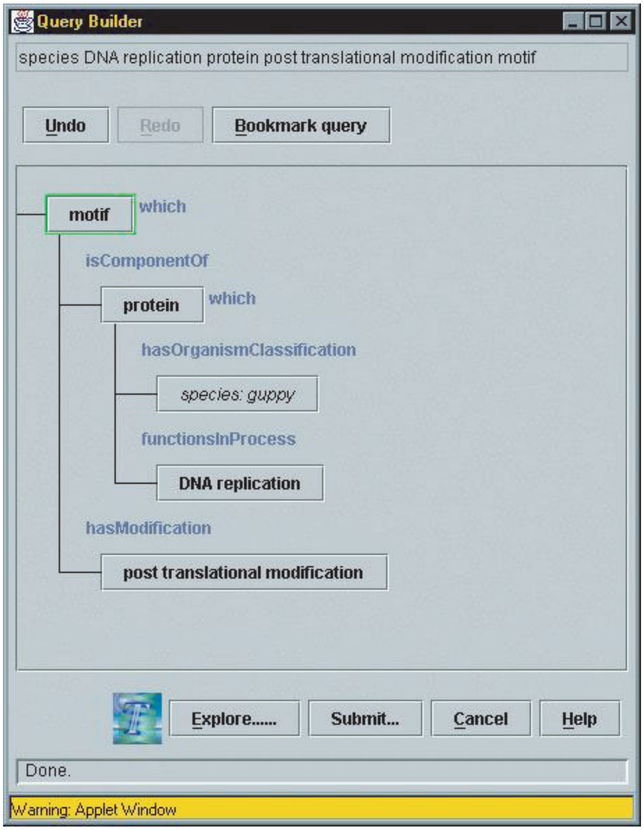

Figure 3 The TAMBIS query-formulation interface

and the wrapped resources in the discoveryHub middleware layer. In broad terms, the SSM maps concepts within the TaO to values representing these concepts held in the resources themselves, and also maps concepts and relationships to functions acting over those resources to retrieve instances. For example, the concept `Kinase` in the TaO maps to the value "kinase" in swiss-prot and "2.27" in ENZYME. In this manner, one concept in the TaO can accommodate the heterogeneous representations of those concepts in the resources themselves. Similarly, the composite concept `Protein hasAccessionNumber AccessionNumber` can be mapped via the SSM to `get-sp-entry-by-ac-no(accession-number)`. The SSM also records resource, parameter, and return types for these functions. Importantly, it also records the cost of executing these functions over the resources, in terms of number of instances returned, of executing these functions over the resources.

The resources swiss-prot, ENZYME, CATH, PROSITE, PROSITE SCAN, and BLAST can be queried using TAMBIS. They are accessed by TAMBIS using discoveryHub's wrapper service. Most bioinformatics resources have no query-language facilities, so requests directed at these resources are represented as a

collection of functions such as `get-sp-entries-by-species` or `get-sp-entries-by-function`. The discoveryHub middleware removes the syntactic or structural heterogeneity pervasive in bioinformatics resources, and the SSM helps remove or manage the semantic heterogeneities of these resources. The TAMBIS query processor (Paton *et al*., 1999) (see Figure 2) takes the high-level conceptual query formulated in the user interface and transforms it to a source dependent, ordered query plan against the wrapped bioinformatics services in discoveryHub. This concrete query plan is expressed in CPL (see Figure 1). The query processor uses a relatively simple algorithm to do this transformation (Paton *et al*., 1999), which relies heavily on the SSM for the transformation:

1. The conceptual query is broken down into a series of components.
2. Each component is matched against the SSM to find the cheapest (in terms of cost) component to fetch.
3. This continues until all query components have been matched against the SSM.
4. This ordered set of components is used to generate CPL code.

This query plan is then executed by the discoveryHub layer and the results presented to the user via HTML markup in a browser.

4. Discussion

TAMBIS tackles the perennial bioinformatics problems of distribution and heterogeneity of resources, both data and tools. The queries possible in TAMBIS are multisource and over distributed resources with heterogeneous APIs, query mechanisms, and semantics. These are typical bioinformatics tasks that require layers of knowledge over the simple computational facilities underlying the query itself. Through its ontology, TaO, TAMBIS provides a conceptual, knowledge-driven query interface over a middleware that allows distributed resources to be included and transformed to a common syntactic interface. The knowledge captured in the TaO enables transparent access to multiple bioinformatics information sources and frees a biologist who is not an expert in bioinformatics to concentrate upon the biological content of his or her query. TAMBIS, linking to the discoveryHub, can be found as an applet via **http://img.cs.man.ac.uk/tambis**. TAMBIS gives the illusion of a common query interface to distributed and heterogeneous bioinformatics resources. Using the TaO, TAMBIS frees biological scientists from the need to hold knowledge of how to answer bioinformatics queries and allows them to capitalize on their knowledge of what questions to ask.

Acknowledgments

Short Specialist Review

Automatic concept identification in biomedical literature

William H. Majoros
The Institute for Genomic Research, Rockville, MD, USA

1. Introduction

While the potential benefits of automatically extracting useful knowledge from biomedical literature are seemingly many and great, nearly all of the techniques that have been considered for doing this rely on a central, nontrivial problem: that of unambiguously identifying the named entities that occur in a particular text. This problem has two parts: (1) identifying the precise boundaries of phrases in a text which refer to biomedical entities and (2) resolving those entity names to known concepts in a knowledge base such as an ontology (Cohen *et al*., 2002; *see also* Article 84, **Ontologies for natural language processing**, Volume 8). These two tasks represent the *syntactic* and *semantic* aspects of the problem, respectively, and though these are not entirely independent in theory, they are often treated as such in practice.

2. Syntactic considerations

One of the computationally simplest approaches to identifying biomedical entities in text is to maintain a lexicon of all the entities of interest and to systematically search through that lexicon for all phrases of any length occurring in a given text. This can be done efficiently by utilizing a data structure based on a *hash table* or a *suffix tree*, with a single pass over the text sufficing to detect all exact matches to phrases in the lexicon. With a sufficiently large lexicon, much can be achieved with this simple procedure, such as primitive *concept-based document retrieval*, or statistical analysis of *co-occurrence patterns* in order to infer possible relationships between entities (Jenssen *et al*., 2001).

But there is also much room for improvement, since many of the named entities in the text will not be found, because either they do not occur in the lexicon or their lexicon entry differs in spelling, word order, hyphenation, or in some other insignificant way from the form that appears in the text. In theory, this shortcoming could be addressed through extensive manual curation of the lexicon so that exhaustive coverage of both concepts and their many lexical variants is

achieved. Unfortunately, this is not practical in many fields both due to the vast number of entities and lexical variants that would have to be curated, and also due to the rapid pace of advance in biomedicine and the constant generation of new concepts that results.

A more sophisticated and promising approach involves the use of *shallow parsing* to identify all noun phrases in a given text. The advantage of this approach is that entities not occurring in the lexicon can at least still be found (to the extent that an accurate parse is obtained), allowing their interpretation to be deferred until semantic information can be curated, inferred, or synthesized for them.

Unfortunately, the accurate identification of noun phrases is itself a difficult problem, especially in the field of biomedicine. A common approach is to apply a *part-of-speech tagger* to mark the nouns, adjectives, and other parts of speech, and then to apply some *chunking* procedure to coalesce appropriate sequences of tagged words into noun phrases. Various techniques have been applied with some success to these two tasks, including the use of rule-based and Markovian systems (Manning and Schütze, 2000).

Although several part-of-speech taggers have been made publicly available, these tend to perform poorly out-of-the-box on biomedical text. Because these are generally trained on generic text such as newswire articles, they have vocabularies and language models that are inappropriate for most specialized domains. As an example, many taggers upon seeing *nucleated erythrocyte* will tag *nucleated* as a verb rather than as a participle, making it very unlikely that this entity will be properly identified as a noun phrase.

Normally, this would be rectified by retraining the tagger on a large corpus of manually tagged text, but unfortunately, such a corpus does not yet exist for biomedicine, and is not likely to exist for some time. The largest publicly available annotated training corpus to date is the GENIA corpus version 3.02 (Kim *et al*., 2003), which contains a mere 2000 of the 12 million abstracts available in MEDLINE. While 2000 full-length documents might be adequate for some domains, these are abstracts only, and were not selected at random. Building a manually annotated corpus of sufficient size to adequately capture the vocabulary and statistical properties of MEDLINE would likely require an inordinate amount of labor.

For this reason, some recent work has explored alternative ways of obtaining an accurate tagger. For example, by utilizing an existing tagger together with the known noun phrases in UMLS (*see* Article 81, **Unified Medical Language System and associated vocabularies**, Volume 8), a training corpus can be automatically synthesized and then used to retrain the original tagger (Majoros *et al*., 2003). In this way, it is conceivable that other automatic or semiautomatic methods might produce useful training data for other parsing strategies.

3. Semantic considerations

Once the named entities have been located in a text, they should, ideally, be mapped then to an ontology in order to link information newly gleaned from the text with what is already known about those entities. Finding exact matches is easy enough,

given the appropriate data structures, but it is the effective detection of inexact matches that is crucial to achieving high sensitivity. This is arguably the most difficult aspect of concept identification.

An example will serve to illustrate some of the difficulties. The gene Apo3 is also variously known as LARD, DR3, TRAMP, wsl, TnfRSF12, and "lymphocyte-associated receptor of death" (Yu and Agichtein, 2003). If any of these are seen in a new text, the occurrences should be resolved to the Apo3 entry in our ontology. Moreover, if our software encounters any of the phrases "lymphocyte-associated receptor of death", "lymphocyte-associated death receptor", or TnfRSF-12, it would be desirable if these also were resolved to Apo3. Yet, to do so requires recognizing that these differences in orthography and word order are insignificant, even though the same types of differences (particularly word order) are certainly significant in other cases.

Thus, a certain amount of domain knowledge must be embedded in a procedure if it is to achieve high accuracy. Among the many features that such a heuristic needs to consider are capitalization, punctuation, spelling, word order, inflection, and the use of acronyms and abbreviations. Any one of these sources of variation might be handled with relative ease, but a complete solution needs to address all of these phenomena. As a result, many of the solutions that have been devised seem somewhat ad hoc, and though a few of them appear to work well on small test sets, it is reasonable to wonder how they will perform on other corpora and whether perhaps a more elegant solution should be sought.

Among the more promising attempts in this direction are those that utilize *machine learning* or statistical techniques (e.g., Leonard *et al*., 2002; Tanabe and Wilbur, 2002). These typically involve the identification of features, such as word morphology or surrounding context, which may be predictive of a given phrase's intended meaning. These approaches seem especially promising for attacking the semantic problem of *concept disambiguation*, in which a single term may conceivably refer to multiple concepts. For example, PSA may refer to *prostate specific antigen*, *psoriasis arthritis*, or *poultry science administration* (Weeber *et al*., 2003), yet it might be reasonably expected that nearby words (such as prostate, psoriasis, or chicken) might facilitate correct disambiguation. Unfortunately, any approach that relies on training is made difficult by the dearth of large, high-quality training sets.

One publicly available tool that appears to perform well (Pratt and Yetisgen-Yildiz, 2003) is MetaMap. This program identifies the noun phrases in a text, generates all lexical variants of all words and subphrases of the noun phrase on the basis of entries in the SPECIALIST lexicon, and then searches through the UMLS ontology for any of the generated variants. Resulting matches are numerically scored and ranked on the basis of match length and other syntactic considerations (Aronson, 2001).

Though semantic resolution of a phrase is not always possible using current methods and ontologies, the unresolved phrases may themselves be of considerable use. Such novel phrases can be appended to lists of terms awaiting manual curation, or they can also be used simply as *uncurated concepts* (perhaps after some clustering or normalization) and subjected to similar types of analyses as curated concepts.

Along a similar vein, automatic means of ontology construction and extension using uncurated resources are receiving considerable attention (e.g., Bodenreider *et al*., 2002; Yu and Agichtein, 2003) as it becomes increasingly clear that truly exhaustive, de novo manual curation will be achieved only at great expense. Most promising, at present, are semiautomatic methods that suggest additions to an existing ontology, which are then subjected to a final manual filtering step. Automated methods for identifying potentially novel synonyms of known concepts include clustering and co-occurrence analyses of known and unknown concepts within a corpus (Blaschke and Valencia, 2002) as well as similarities in phrase morphology (Pustejovsky *et al*., 2002). In the case of the latter, variant generation procedures similar to those employed by MetaMap can be used to suggest not only synonyms but also prospective hyponyms in the case of known concepts which are observed with novel modifiers in a corpus, such as *erythrocyte* and its hyponym *nucleated erythrocyte.* More sophisticated approaches are possible which utilize existing knowledge to infer novel relationships. For example, if *adipocyte differentiation* occurs in a corpus but is absent from the ontology, then we might infer that it is a hyponym of the known concept *cell differentiation*, given that *adipocyte* is a known hyponym of *cell*.

4. Outlook for the future

Much room remains for progress on virtually all fronts of the concept-identification problem. In order to enable further advances, more effort needs to be invested in producing large, diverse, high-quality annotated corpora and ontologies, both for training concept-identification programs, and to provide standard test sets for comparisons. The availability of open-source software will likewise accelerate advancement in this field as researchers are enabled to perform more controlled experiments comparing different algorithms within the same software configuration.

Short Specialist Review

Merging and comparing ontologies

Natalya F. Noy
Stanford University, Stanford, CA, USA

The use of formal systems to define biomedical concepts and to represent and store biomedical knowledge has never been more important to the informatics community. The past decade of research has seen a growing consensus regarding the critical nature of controlled terminologies and well-defined ontologies in the construction of all information systems. From the implementation of hospital information systems to the organization of experimental data for research in bioinformatics, developers now identify the key issue to be the manner in which salient concepts are labeled and defined, and ultimately used computationally.

In the past few years, ontologies have become the cornerstone of the information-systems research. While there is no single agreed-upon definition of an ontology, the one that is cited most frequently is the definition by T. Gruber (1993): "ontology is an explicit formal specification of conceptualization." For the purposes of this article, we define an ontology as a set of concepts that categorize an application area (classes), their attributes, relations between concepts, and constraints on these relations. There is also often instance data associated with an ontology, which are individual examples of these concepts with some or all of the attributes and relations specified.

With the wider use of ontologies, the problem of *ontology management* began to arise: ontology developers and users must be able to find and compare existing ontologies or their parts, merge and align ontologies, compare different versions, and translate ontologies from one formalism to another. Only recently have researchers started to address these problems, in large part because until ontologies came into widespread use, their management was not a serious issue.

It is impractical to assume that eventually there will be one single set of standard ontologies that everyone will conform to. In fact, experiences, even in such a mature field as industrial databases, show that having a small set of standard schemas and ontologies is still unattainable: it is not uncommon for a single large enterprise to use more than a dozen database schemas for purchase orders, for example. There are many reasons for someone to develop his own ontology or schema rather than to reuse an existing one. These reasons range from proprietary and institutional reasons (e.g., an institutional requirement to use only components developed in-house) to more practical reasons: if the task is not a standard task, it may be easier

to develop a custom-tailored ontology just for that task than to reuse and adapt an existing one.

We start by considering various ontology-management tasks and the corresponding tools separately (Klein, 2001). Systems such as PROMPT (Noy and Musen, 2000) and Chimaera (McGuinness *et al*., 2000) support *ontology merging* – creating a single coherent ontology from source ontologies that covered similar domains. Systems such as ONION (Mitra *et al*., 2000) and GLUE (Doan *et al*., 2002) look at the issue of finding *mappings* between concepts in different ontologies. Researchers in the SHOE group (Heflin and Hendler, 2000) worked on approaches to *ontology versioning*, defining what it means for a new version of ontology to be backward compatible with the old one.

This research has produced a plethora of interesting approaches and heuristics for finding differences and similarities between ontologies. In fact, as we discussed in our earlier review of the field (Noy and Musen, 2002b), approaches are so different and rely on such different assumptions about the source ontologies that it is hard to compare them. The user must choose the appropriate set of tools on the basis of the specific type of ontology and data that he has at hand. For instance, some approaches relied on instance data to find correspondences between concepts in different ontologies. They use the values in the instance data to infer correspondences between classes of these instances. Thus, these approaches can be used only when there was instance data corresponding to the ontologies. However, since ontologies are often developed to describe the domain and used directly in an application or used as a controlled terminology to annotate other ontologies and data, instance data is not always available. If instance data is available, however, approaches that use it to find correspondences are very beneficial.

Other approaches consider class definitions to find which concepts in one ontology correspond to concepts in another. First, one can lexically compare class names and infer that classes with similar names probably correspond to similar concepts. This approach, however, is not without peril since even if ontologies covered the same domain of discourse, classes with similar names may actually describe different concepts. Consider a class University for example. It could mean a university campus, or university as an organization with its departments, faculty, and so on. Furthermore, ontology designers often use different words or combinations of words to mean the same concept. This – approaches that looked up dictionaries and thesauri – proved useful in finding these types of similarities.

The next generation of tools that had to compare two ontologies used more than just names of classes, and used the structure of class definitions to find parallels. For instance, if two classes had similar names but also a similar set of properties and superclasses, then they were more likely to be similar than two classes, where only the names correlated. Further, tools used the input provided by the users of interactive merging and mapping tools in their analysis as well. For instance, if our algorithm already suggested that two classes were similar and then the user explicitly said that their superclasses are the same, our confidence in the suggestion is much stronger.

Finally, a number of algorithms looked at ontologies as graphs and compared the graphs looking for similar subgraphs indicating similar concepts (see e.g.,

ANCHORPROMPT (Noy and Musen, 2001) or Similarity Flooding (Melnik *et al*., 2002)).

There have been fewer tools for ontology versioning than one might expect, given the collaborative nature of ontology development. Tools for managing versions of software code, such as CVS (**http://www.cvshome.org**), have become indispensable for software engineers participating in dynamic collaborative projects. These tools provide a uniform storage mechanism for versions, the ability to check out a particular piece of code for editing, an archive of earlier versions, and mechanisms for comparing versions and merging changes and updates.

Ontologies change just as a software code does. These changes result from changes in the domain itself (our knowledge about the domain changes or the domain itself changes) or in the conceptualization of the domain (we may introduce new distinctions or eliminate old ones). Furthermore, ontology development in large projects is a dynamic process in which multiple developers participate, generating different versions of an ontology. Naturally, collaborative development of dynamic ontologies requires tools that are similar to software-versioning tools. In fact, ontology developers can use the storage, archival, and checkout mechanisms of tools such as CVS with very little change.

There is one crucial difference, however: Comparison of versions of software code entails a comparison of text files. Program code is a set of text documents and the result of comparing the documents – the process is called a *diff* – is a list of lines that differ in the two versions. This approach does not work for comparing ontologies: two ontologies can be exactly the same conceptually, but can have very different text representations. For example, their storage syntax may be different. The order in which definitions are introduced in the text file may be different. A representation language may have several mechanisms to express the same thing. Therefore, text-file comparison is largely useless in comparing versions of ontologies. As a result, tools such as OntoVIew (Klein *et al*., 2002) and PromptDiff (Noy and Musen, 2002a) were developed. The former enables ontology developers to specify conceptual details of how exactly the concept definitions have changed (e.g., a concept became more general).

The latter uses a set of heuristics to find which parts of an ontology remained unchanged and which were added, deleted, or redefined. The crucial observation on which it relies is that, unlike with different ontologies, in versions of the same ontology, terms with similar names are much more likely to mean the same thing. For instance, a class University in two versions of the same ontology is unlikely to refer to the campus in one and organization on the other. The heuristics that PromptDiff uses enable it to achieve remarkable accuracy in finding differences between the two versions.

Interestingly, each of the tools that we have described addressed only one of the ontology-management problems: ontology merging, ontology mapping, or comparison. As more of these tools and algorithms appeared, however, it became clear that most ontology-management tasks share the same problems and if we could solve one of them, we could have great insights for solving another. Essentially, all of these tasks require finding similarities and differences between two ontologies. When we are merging two ontologies, for example, we need to merge the parts that are similar and just bring along the remaining, different parts (making sure our

merged ontology is still logically consistent, of course). When we need to translate data from one ontology to another, we again need to know what the similarities are and translate instance data corresponding to a class in one ontology to the instance data to the class that is similar to it in another ontology. The same is true for answering queries posed in terms of one ontology with data from another ontology: we need to look for similar concepts in the other ontology. If we are comparing two versions of the same ontology, we are interested in examining the differences rather than the similarities, but this problem can be treated as the complement of finding similarities, and it is certainly amenable to the same techniques.

P. Bernstein and colleagues capitalized on this observation, developing a general theory of model management (Bernstein *et al*., 2000). At the center of the theory is a notion of a *mapping*, which can be applied to structured models of different kinds (not only ontologies but also XML schemas, database schemas, etc.). The mappings are first-class objects that can then be used for tasks such as merging, data transformation, or query answering. Similarly, Noy and colleagues (Noy and Musen, 2004) suggested a generic framework for ontology-management tasks. The same algorithms are used for ontology merging, mapping, and comparison, but with different thresholds for confidence values.

The cross-fertilization between techniques used for different ontology-management tasks proved very productive, and we believe that in the future this general approach to various tasks involving several ontologies will become the foundation of a new generation of sophisticated tools.

Short Specialist Review

Bioinformatics pathway representations, databases, and algorithms

Peter D. Karp

Bioinformatics Research Group, Menlo Park, CA, USA

1. Introduction

Gene products affect living systems through carefully orchestrated cascades of molecular interactions known as pathways. For example, metabolic pathways transform small molecules through a sequence of enzyme-catalyzed reactions that produce energy and that synthesize the chemical building blocks of the cell. Signaling pathways are sequences of interactions among proteins that enable a cell to respond to changes in its environment, such as by altering gene expression.

Management of pathway information is of great importance in bioinformatics because pathways place gene products in a causal, mechanistic context showing how those gene products contribute to a larger biological process, and allow us to reason about perturbations to a living system. In the postgenomic era, pathways are also an important organizational and information-reduction device that decreases the cognitive complexity of a biological system by allowing us to reason about a system at the level of pathways instead of at the level of proteins.

Management of pathway data is a challenging area of bioinformatics because it involves a host of representational and algorithmic problems.

2. Pathway representations

We define a pathway as a cascade of biochemical interactions. Thus, interactions (biochemical reactions) are the building blocks of pathways, in the sense that pathways are built by linking interactions together in sequence. Molecules are the building blocks of interactions, in the sense that interactions are built from the molecules that comprise their reactants and products. For metabolic pathways, those molecules are small-molecular-weight chemical compounds, whereas for signaling pathways, those molecules are often proteins.

The pathway representation developed for the EcoCyc database (DB) (Karp, 2000) takes literally this three-tiered layering in the sense that pathways, interactions, and molecules are all represented as separate DB objects in the EcoCyc

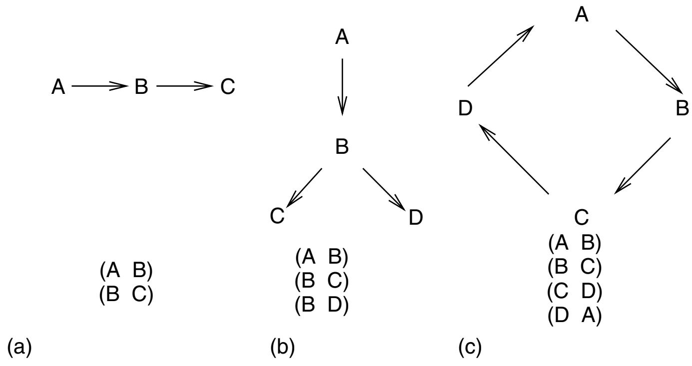

Figure 1 This figure shows three simple pathways, and the corresponding predecessor lists used to encode them (below)

representation, and pathways are built from interactions, which in turn are built from molecules. In addition to facilitating the three-tiered representation, this separation produces a nonredundant representation in which the data about a single chemical compound is represented only once in the DB, even though that chemical compound might be a reactant or a product of many different chemical reactions. Similarly, a given reaction is represented once in the DB even though it might be a component of several different pathways. Nonredundancy is a central principle of DB design because it minimizes data entry and ensures that updates to information about a given object need occur in only one place.

The simplest form of a pathway is a linear cascade – a sequence of biochemical events in which the output of the first event becomes the input of the next event. In a linear metabolic pathway, for example, consecutive steps in a pathway share a common small-molecule substrate, such as molecule B shown in Figure 1(a). Pathways come in a variety of topologies including linear pathways, tree-structured pathways, circular pathways, and combinations thereof.

Karp and Paley developed a representation called the *predecessor list* that allows us to represent the topology in which the interactions that comprise a pathway are linked. The predecessor list specifies the ordering between all adjacent pairs of interactions within a pathway. It is a list of tuples, where each tuple (A B) specifies that reaction A is the predecessor of reaction *B* in the pathway, that is, reaction B follows reaction A in the pathway, and that the two reactions share a common substrate. Figure 1 shows the predecessor lists used to represent linear, circular, and tree-structured pathways.

Each reaction within a pathway is represented as a separate object whose properties encode lists of reactants and substrates for the reaction, and properties such as the EC number and equilibrium constant of the reaction. Each substrate is represented as an object whose properties can include the chemical formula and chemical structure of the substrate.

Pathway representations should capture the many-to-many relationship between enzymes and the reactions they catalyze. Reactions and enzymes must be separate objects within the DB to ensure that the properties of the reaction are captured separately from the properties of the protein (such as its subunit structure and

physicochemical properties). Because a reaction can be catalyzed by multiple isozymes, and because an enzyme can catalyze multiple reactions, there must be an explicit mapping between each enzyme and the reaction(s) it catalyzes.

The definition of pathways is a useful mechanism for dividing a complex network of metabolic reactions into more understandable units. Pathways have biological meaning because they are often regulated as a unit, their genes are often grouped together on the chromosome as a unit in bacteria, and they are conserved through evolution as units. However, in some computational contexts it can be useful to ignore the pathways defined in an organism and compute across the metabolic network as simply a set of interconnected reactions. The preceding representation completely supports this viewpoint since the reaction set of an organism can be queried independently of the pathways to which those reactions have been assigned.

Petri nets provide another formalism for representing networks of biochemical reactions (Peterson, 1981; Peleg *et al*., 2002; Mandel *et al*., 2004). Petri nets are a directed graph–based representation in which two types of nodes are defined: places (corresponding to reaction substrates) and transitions (corresponding to reactions). Vertices of the graph connect places and transitions to define the reactions that operate on each substrate. Each place contains a state descriptor consisting of a number of tokens, which can represent the concentration of the corresponding substrate.

A number of computational operations have been defined on Petri nets including modeling the flow of material through a network, and determining properties of a network such as liveness (all transitions can occur), boundedness (the number of tokens at every place will be bounded by some ceiling), and reachability (can some final state of the network be reached from a starting state of the network?).

Note that there is a straightforward mapping from the first representation described above to Petri nets – each substrate maps to a place and each reaction maps to a transition – allowing the algorithms developed for Petri nets to be applied to databases structured using the preceding representation.

3. Pathway databases

SRI's BioCyc collection of pathway DBs includes 16 DBs that describe the metabolic pathways of specific organisms, and the MetaCyc DB of 500 experimentally determined metabolic pathways from more than 200 organisms.

The BioCyc philosophy is that we should model the metabolic network of each distinct organism of interest in a separate organism-specific DB to provide maximum accuracy. These organism-specific DBs are created in two phases: in Phase 1, we predict the metabolic network using the PathoLogic algorithm. In Phase 2, this computational prediction is refined through a literature-based curation process in which new pathways are manually added to the DB, and predicted pathways are edited to reflect organism-specific variations in the pathways.

The computational pathway prediction process depends on the MetaCyc DB, which provides a reliable reference set of experimentally defined metabolic pathways. MetaCyc enzymes and pathways are all derived from the experimental literature, and are curated with copious comments and citations to 4550 literature references.

Other pathway DBs include KEGG (Kanehisa *et al*., 2002; *see also* Article 101, **Design of KEGG and GO**, Volume 8), WIT (Overbeek *et al*., 2000), and Amaze (van Helden *et al*., 2001).

BioPAX is a standard for encoding and interchange of pathway data. It describes a common ontology for pathway data, and supports encoding of pathway data within the XML-based OWL language, which is a basis for the Semantic Web. See **http://www.biopax.org/**. The Systems Biology Markup Language (SBML) is a standard for representing models of biochemical reaction networks (see **http://sbml.org/**). SBML is applicable to metabolic networks, cell-signaling pathways, regulatory networks, and many others.

The BioPathways Consortium (see **http://BioPathways.org**) is dedicated to catalyzing the development of pathway bioinformatics. The consortium organizes workshops and presentations at a number of bioinformatics and biology conferences.

4. Pathway algorithms

Pathway algorithms are a core component of Systems Biology. Systems Biology seeks to understand the workings of a biological system from the interactions of its components, and many of those interactions occur through pathways. It is instructive to differentiate Symbolic Systems Biology from Quantitative Systems Biology. The latter is concerned with qualitative questions that can be answered through symbolic computations, such as: What biochemical reactions and pathways are present in an organism? How can we fill holes identified in that network? What end products can be produced by the network given a specified set of input compounds?

Quantitative Systems Biology is concerned with quantitative computations such as predicting equilibrium fluxes through a metabolic network, or predicting the time course of behavior of a biological network.

4.1. Pathway prediction

Pathway prediction algorithms predict the existence of pathways within an organism. Prediction by similarity predicts the presence in one organism of pathways with the same reaction topology as pathways previously known in other organisms. For example, the PathoLogic algorithm predicts the presence of pathways from the MetaCyc DB in an organism whose genome has been sequenced (Paley and Karp, 2002). The essence of the algorithm is to match enzyme activities identified in the genome (matching via both enzyme name and EC number) to enzymes in MetaCyc pathways. Pathways for which a significant number of enzymes are present are predicted to be present in the organism being analyzed.

De novo prediction algorithms predict the existence of pathways that were not previously known in other organisms. The algorithm of Shah *et al*. (McShan *et al*., 2003) predicts pathways that synthesize a user-specified product metabolite from a user-specified ending metabolite. The algorithm considers known reactions from a supplied reaction DB, and uses an A^* search to find optimal pathways. The method defines a search space whose nodes are chemical compounds and whose edges are

known reaction transformations. The cost function used to evaluate pathways is based on chemical differences between the intermediate compounds.

4.2. Pathway hole filling

Pathway networks predicted from genome information are typically incomplete in the sense that some of the reactions in some pathways have no enzyme identified in the genome that catalyzes that reaction. The algorithm of Green *et al*. generates hypotheses as to which genes in the genome code for enzymes that catalyze these "pathway hole" reactions (Green and Karp, 2004). The algorithm works by retrieving protein sequences for other enzymes that catalyze that same biochemical reaction in another species, and then BLASTing those sequences against the genome to generate candidate genes. The candidates are evaluated with a Bayesian network that generates a probability score for the correctness of each candidate.

4.3. Flux-balance analysis

Once a metabolic network has been reconstructed for a genome, it is possible to compute a number of aggregate properties of the network.

Computational flux-balance analysis (FBA) (Kauffman *et al*., 2003; Segre *et al*., 2003) can predict the equilibrium fluxes through each reaction in the network. The method works by defining a set of constraints across the whole metabolic network and then solving an optimization problem across those constraints. The constraints typically specified in FBA models include mass balance across the entire metabolic network (i.e., the sum of all reaction fluxes cannot yield a net change in chemical mass), optimization of cell growth rate given the available biomass, and constraints on the chemical composition of the cell based on past measurements of that composition. FBA can not only produce accurate predictions of reactions fluxes, but in many cases can predict which enzyme-coding genes are essential for cell growth.

4.4. Forward propagation through a metabolic network

An important type of qualitative question regarding a metabolic network is: given a specified set of compounds as inputs to the network, what outputs can the network produce? Note that we have not asked about the rates at which these outputs are produced (which requires extensive knowledge of quantitative network parameters), but simply: what outputs *can be produced?* This calculation can serve as a validation of the reconstructed network if the given input is a known growth medium for the organism, in which case the reconstructed network should be able to produce all small-molecule compounds essential for life (including the building blocks of protein, DNA, RNA, etc.).

Intuitively, an algorithm can solve this problem by determining whether a path can be traced through the metabolic network from the starting compounds to the output compounds. If a compound is not reachable through the web of metabolic

reactions, then the cell will be unable to produce that compound. But strictly speaking, reachability through the network is not a sufficient condition for the algorithm to evaluate because a biochemical reaction requires *all* of its reactants to be present for that reaction to be active. Therefore, the algorithm devised by Romero and Karp (2001) converts a set of biochemical reactions to a *production-rule system* and converts the set of input metabolites to the initial axiom set for that production system. A reaction of the form $A + B \rightarrow C$ is converted to a production rule of the form $A \wedge B \supset C$. The algorithm repeatedly searches for rules whose left sides are satisfied and fires a rule by adding the species on the right side of the rule to the current pool of metabolites. For example, the preceding rule would fire when A and B are present in the metabolite pool, adding C to the metabolite pool. A and B would be present in the metabolite pool if they were either in the initial axiom set, or they were created by the firing of a production rule. This algorithm was able to verify that the *E. coli* metabolic network modeled by the EcoCyc DB can produce a set of 40 metabolic building blocks, given a set of input metabolites that constitutes a known growth medium for *E. coli*.

4.5. *Simulation of biochemical systems*

In recent years, a large number of software tools have been developed for simulation of biochemical systems (Pettinen *et al*., 2004; *see also* Article 102, **Simulation of biochemical networks**, Volume 8). The Bio-SPICE (Garvey *et al*., 2003) and Systems Biology Workbench (SBW) (Sauro *et al*., 2003) projects have developed software architectures for integrating these tools into a smoothly interoperating collection that supports construction of simulation models, execution of those models by solver programs, and interpretation of results. For example, the Bio-SPICE Dashboard uses a distributed services discovery and invocation mechanism to permit data sources, models, simulation engines, and output displays provided by different investigators and running on different machines to work together across a network.

Tools supporting graphical interactive construction of simulation models allow users to define the reactions and pathways within a differential-equation based model, and the substrate concentrations and enzyme parameters for the model. Example tools include JDesigner (Sauro, 2001) and Kinetikit (Bhalla, 2002).

Model-execution systems simulate the time-series behavior of a model using a numeric integration package. Example simulators include Jarnac (Sauro, 2000), Gepasi (Segre *et al*., 1997), E-CELL (Tomita *et al*., 1999), and the JigCell Run Manager (Allen *et al*., 2003). Some systems include tools for estimating values of unknown parameters – Gepasi has a particularly comprehensive collection.

Interpreting the results of a simulation and comparing those results with other simulations or with experimental observations is a subject for other tools, such as the JigCell Comparator (Allen *et al*., 2003) and the E-CELL user interface.

Short Specialist Review

Proteomics data representation and management

Norman W. Paton, Andrew Jones and Stephen G. Oliver
University of Manchester, Manchester, UK

1. Introduction

Bioinformatics tools and techniques depend directly or indirectly upon experimental data. However, interpretation of experimental data often requires access to significant amounts of additional information about the sample used, the conditions in which measurements were taken and the laboratory equipment used. Recent proposals for models that capture such experimental descriptions alongside results include MAGE-ML for transcriptome data (Spellman *et al*., 2002) and PEDRo for proteome data (Taylor *et al*., 2003). The description of a proteomics investigation is challenging, as the range of available experimental techniques is both extremely broad and rapidly evolving. Therefore, although there are well-established data resources for reference maps (Hoogland *et al*., 2004), such resources tend not to contain enough information to enable scientists to validate the techniques used to produce a result, or to allow for the comparison of results from different laboratories. In addition, the cost of producing such large data sets is very high because the experiments rely upon complex instruments that require substantial technical expertise. Therefore, it is imperative that experimental data are available for reanalysis and querying in various ways. While experimental results can be analyzed in-house, often in a labor-intensive manner, the development of bioinformatics techniques for archiving, sharing, and wider exploitation of proteomics results is still in its infancy.

2. Proteomics data sources and users

Establishing the most appropriate kinds of data to include in a proteomics database is not straightforward, as this depends on the use that is to be made of the data. In a large data repository, users may want to search for results based on widely varying criteria – for example, the proteins identified, the change in the level of a protein over time, the mechanism by which a sample was studied, and so on. Furthermore, the users of a proteome data repository may themselves be diverse,

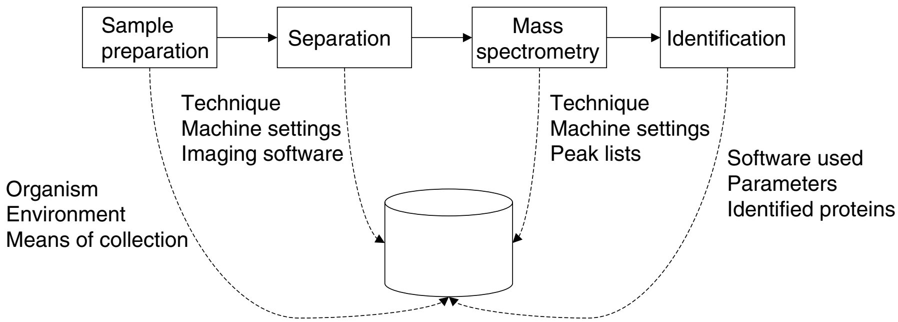

Figure 1 The stages in a proteomics experiment, plus the associated data

and include experimentalists with minimal direct experience of proteomics, but who are interested in proteins or organisms for which proteome studies have been conducted; proteome scientists who want to identify how successful specific techniques have been in different contexts; or mass-spectrometric analysts who want to compare their results with those of others.

Figure 1 illustrates the components of a typical proteomics experiment. The different components of such a pipeline give rise to data that must be captured in a systematic manner if it is to be readily interpreted, shared, or analyzed. The kinds of information emerging from each aspect of the experiment are:

1. *Sample preparation*: The starting sample is any kind of biological material, from a single organelle, up to cell cultures, tissues, organs, or whole organisms (*see* Article 2, **Sample preparation for proteomics**, Volume 5). The sample description must be captured because the proteome is highly dynamic and dependent upon the environmental conditions and the genotype of the organism. A complex mixture of proteins is extracted from the sample and dissolved in solution. The experimental procedure for protein extraction is highly variable and depends upon the type of sample.
2. *Separation*: The principle of separation is to make use of the differences of a particular property between individual protein species, such as the molecular weight (MW), charge, or hydrophobicity. Details of this process affect which proteins may be detected in a sample, and thus are crucial to the interpretation of experimental results. The techniques of one-dimensional or two-dimensional gel electrophoresis (1-DE/2-DE) utilize an electric current to resolve individual proteins into single bands by MW (1-DE) or into discrete spots by MW and charge (2-DE) on a gel (*see* Article 29, **Two-dimensional gel electrophoresis (2-DE)**, Volume 5). The separation stage can produce quantitative measures of protein volume. For example, a gel can be scanned, and image-processing software can estimate the relative volume of a particular protein between different conditions by comparing the corresponding spots across multiple gels. Liquid chromatography (LC) separates proteins in a column filled with a solution through which proteins pass in a variable length of time. Two sequential LC stages can be coupled to resolve proteins at a high definition. Gel spots or column fractions can be treated with a protease that digests proteins into peptides, which

can be analyzed by mass spectrometry for protein identification. An alternative approach in proteomics is to cleave the entire protein mixture into peptides as a first stage. The peptides are then separated by two-dimensional liquid chromatography and applied directly to tandem mass spectrometry (described below). This approach can be used for high-throughput analysis because there are very few manual handling stages.

3. *Mass spectrometry*: The output from mass spectrometry (MS) can be used to identify proteins. The pattern of molecular weights of a set of peptides can often uniquely identify a protein following its digestion with a protease: *the peptide mass fingerprint* (*PMF*). In other cases, individual peptides are collected and cleaved into fragments that allow their amino acid sequence to be determined (tandem MS or MS/MS). A mass spectrometer can have a number of input parameters that must be captured. MS produces raw data, which is a list of X/Y coordinates, also known as a peak list. The peak list can be processed automatically or manually edited to remove noise from the data.
4. *Identification*: There are a number of database search applications that identify proteins on the basis of MS data. The peak list is entered, and the software has a number of optional parameters that affect the results. The output includes the peptides within each sequence that have been matched by their molecular weight (PMF) or by their partial or complete amino acid sequence (MS/MS). There is usually a statistical score to indicate the likelihood of correct protein identification but the score is not standardized across different applications. Therefore, the software used, the input parameters and the version of the database searched must be captured to allow the identification to be externally verified.

Several of these individual sources of data are challenging to model because of the diversity or complexity of the techniques used. For example, there are a number of software applications used for database searches and for gel image analysis, which produce nonstandard output values. The phenotype of a sample is particularly difficult to model because the source of a sample and its environmental history is effectively unlimited. There are also frequent developments in technology for protein separation (Washburn *et al*., 2001) and for quantifying the volumes of proteins on a large scale (Gygi *et al*., 1999).

3. Proteomics data management

Given an understanding of the data that must be captured, there is still a question as to the nature of the data management systems and tools that can most effectively be used to capture, store, and manipulate the experimental data. In some cases, a representation can be developed to address a specific task. For example, the molecular interaction format (Hermjakob *et al*., 2004) developed by the Proteomics Standards Initiative (PSI) (*see* Article 61, **Data standardization and the HUPO proteomics standards initiative**, Volume 7) of the Human Proteome Organization (HUPO) was designed principally to support the exchange of data between different protein-interaction databases (*see* Article 44, **Protein interaction**

databases, Volume 5). As such, an implementation of the representation using XML (**http://www.w3.org/XML**) provides direct support for sharing of interaction data, while leaving open the question as to how the data should be stored for analysis purposes. Another example of an XML representation for proteomics data is mzXML (Pedrioli *et al*., 2004), which is used as an intermediate representation for data from mass spectrometers, which has traditionally been represented using proprietary formats. The mzXML representation is associated with a library of format conversion and analysis programs, which tend to assume that the XML data is stored as files in a file system. However, such representations support less flexible access than database systems, and PEDRoDB (Garwood *et al*., 2004) provides an early example of a repository in which an XML database is used to support storage and searching of proteomics data directly in XML. An advantage of using an XML database system is that there is no need for complex mappings to be developed and maintained from XML into alternative data models, such as relational databases. A corresponding disadvantage is that there is less community experience relating to the management of large XML repositories, and current XML databases may not be able to match relational databases in terms of data security and query performance.

As such, there is a need to identify the role that a proteomics repository is to fulfill, and to select a model and information management infrastructure to match these needs. Objectives for a proteomics data repository could be:

1. To allow the results of different experiments to be analyzed and compared.
2. To enable queries at the level of individual proteins, biochemical pathways, tissues, or whole organisms.
3. To allow the suitability of experiment design and implementation decisions to be assessed.
4. To allow protein identifications to be rerun in the future with new databases or software.
5. To include sufficient detail about the equipment and settings used to enable replication of an experiment.

Different proteome data management systems can be expected to support different levels in the above, depending on their anticipated user requirements and the resources available for data capture and storage. For example, SWISS-2DPAGE (Hoogland *et al*., 2004) currently focuses on (1) and (2), and PEDRoDB (Garwood *et al*., 2004) seeks to support (1) to (4). As integrative studies that produce data at the levels of transcriptome, proteome, and metabolome become more common, it will become essential that the data management systems for all three types of data incorporate a uniform system to describe sample origins.

Short Specialist Review

Ontologies for three-dimensional molecular structure

John Westbrook and Helen M. Berman
Rutgers, The State University of New Jersey, Piscataway, NJ, USA

1. Introduction

Structural biology has witnessed an enormous increase in the amount and types of data collected by both experimental and computational methods. Data ontologies provide an important underpinning for the informatics infrastructure supporting structure and biological data. These ontologies provide precise definitions and examples, controlled vocabularies, allowed ranges and boundary conditions, data types, and data relationships (e.g., parent–child/foreign key). Data ontologies are required to support key informatics tasks such as the accurate acquisition information, data exchange including format conversion with semantic precision, database schema definition, application program interface definition, and data documentation.

Data ontologies can be expressed in many concrete formats and are not bound to a particular technology. In creating an appropriate ontology, the underlying data model must be adequate to represent the scientific content. It must also be widely accessible to users in that it must be easy to understand and extend, and it needs to be supported with reusable software tools. Three-dimensional (3 D) molecular structure data presents a variety of challenges in data representation. Approaches that have been used to address these challenges for small and macromolecular structure data are described.

2. Representation of small molecule structure data

2.1. CIF

Comprehensive descriptions of experimental details and 3 D structural results from X-ray diffraction studies of small molecules have been created as part of the Crystallographic Information File (CIF) project (Hall *et al.*, 1991). CIF data dictionaries describing experimental and structural details of single-crystal diffraction, powder diffraction, and incommensurately modulated structures are maintained by a standing committee of the International Union of Crystallography (IUCr) (International Union of Crystallography, 1998). These dictionaries contain data definitions

representing experimental data collection and reduction, phasing, refinement, 2 D (two-dimensional) chemical structure, 3 D coordinates, geometrical features of the resulting chemical structure, and a description of stereochemical quality.

The CIF data dictionaries are organized according to a Dictionary Definition Language (DDL) (Hall, 1998), which defines metadata attributes such as semantic definitions and examples, data type, controlled vocabularies, range restrictions, physical units, and functional relationships (e.g., mean and associated uncertainty). This dictionary metadata can be exploited by software to validate the logical consistency of a CIF data file.

The CIF data representation is used by the archival repositories for organic and inorganic small molecules – the Cambridge Crystallographic Data Center (CCDC) and the Inorganic Crystal Structure Database (ICSD) respectively. The CIF format also serves as an electronic publication format for the IUCr journal *Acta Crystallographica Section C*. Over 95% of the manuscripts describing small molecule structure determinations are submitted to this journal as CIF data files.

2.2. *CML*

The Chemical Markup Language (CML) project (Murray-Rust and Rzepa, 1999) provides an XML-based representation of small molecule chemical structure, and has announced plans to represent both 2 D and 3 D chemical structure, results of electronic structure calculations, chemical reactions, some physiochemical properties, and spectra. CML is described as an XML DTD or schema; however, the current core schema (v 2.1.1) documents only a portion of the proposed content.

2.3. *The SDF format*

Perhaps, the most pervasive representation of 2 D and 3 D small molecule chemical structure is that used within the SDF file format (Dalby *et al*., 1992). The SDF representation contains 3 D coordinates, a connection table describing bonding information, and stereochemistry. Complex chemical reactions and reaction intermediates can also be represented within an SDF file. This file format is widely used to exchange small molecule structure data between cheminformatics databases.

2.4. *Molecular identifiers*

An important issue in the representation of small molecule structure data is the assignment of a unique identifier to each molecule. Owing to the complexity in systematic nomenclature and the many common molecular naming systems, the use of molecular names as unique identifiers is problematic. Unique signatures based on chemical structure including stereochemistry have been developed to address this issue. The Simplified Molecular Input Line Entry Specification (SMILES) (Weininger, 1988) is one approach that has been used to create a canonical string

representation of chemical structure. Typically, a SMILES string is produced by a software tool using input from an SDF format file or a similar chemical description. IUPAC has recently started a project to create a standard unique identifier for small molecules called the *IUPAC Chemical Identifier* (*IChI*) (IUPAC, 2001). A preliminary implementation of an SDF to IChI conversion tool is available.

3. Representation of macromolecular structure data

3.1. The PDB format

The most widely used representation of macromolecular structure is that provided by the Protein Data Bank (PDB) (Berman *et al*., 2000) file format. This format was developed in 1972, and shares the column-oriented punch card style, typical of data formats of this period. In addition to the 3 D coordinates for each macromolecular structure, a PDB data file includes functional assignment, molecular names, biological source, chemical sequence, secondary structure, transformations required to construct a biologically functional assembly, references to related sequences, experimental details of crystallization or sample preparation, data collection, and refinement. The latter experimental details are reported in the form of unstructured or semi-structured text remarks. The content of the PDB format is documented in the PDB Content Guide: Atomic Coordinate Entry Format Description (Callaway *et al*., 1996).

3.2. mmCIF

In 1990, the IUCr formed a working group (Fitzgerald *et al*., 1992) to extend the small molecule CIF dictionary with data items relevant for the macromolecular crystallographic experiment. Initially, the hierarchical nature of macromolecular structure and experiment was difficult to represent using the DDL employed in the small molecule core CIF dictionary. To address this issue, a more structured DDL was adopted for the macromolecular dictionary, DDL2 (Westbrook *et al*., in press-b). DDL2 added language extensions to include all of the expressivity of the relational data model. This permits the required specification of uniqueness and for correspondences between primary and foreign keys. With this extension, the parent–child relationships between structure identifiers (such as chain identifier, residue name, and atom name) that are reused throughout the dictionary could be properly described, and these relationships could then be rigorously validated in software, using only the data dictionary.

After much community input and review, the first version of the macromolecular Crystallographic Information File (mmCIF) (Bourne *et al*., 1997; Westbrook and Bourne, 2000) dictionary was released in 1997. This version incorporated community-vetted definitions for experimental X-ray crystallographic concepts and definitions describing macromolecular structure and crystallographic experimental details included in the PDB at that time. A standing committee of the IUCr oversees the maintenance and extension of the mmCIF dictionary.

3.3. The PDB exchange data dictionary

The PDB adopted mmCIF and its supporting metadata architecture to represent the data that it collects and distributes. The PDB Exchange data dictionary (Westbrook *et al*., in press-a) provides a comprehensive and precise specification of the data content of the PDB. This data dictionary incorporates the full content of the mmCIF dictionary. Extensions are included for NMR, cryo-electron microscopy, structural genomics, protein production, and data extraction. The latter extensions define quantities that may appear in the outputs of structure determination applications. Careful definition of these data permits the automated software extraction of this information and inclusion of this information into the PDB deposition stream.

The PDB Exchange dictionary is also provided in the form of an XML schema (wwPDB, 2004).

3.4. NMR

The BioMagResBank (BMRB) (Ulrich *et al*., 1989) is the archival repository for NMR experimental data. The focus of this data resource is the collection of experimental NMR data (e.g., chemical shift data). The BMRB also includes a description of 3 D macromolecular structure in their data representation. Using a related but slightly different syntax, BMRB developed a data dictionary named NMRSTAR (BioMagResBank, 2004). NMRSTAR has recently been translated to a form that is compatible with the mmCIF style data dictionary (NMRIF). This has facilitated the exchange of data and dictionaries between crystallographic and NMR users and between the PDB and BMRB databases.

3.5. Cryo-electron microscopy

Cryo-electron microscopy is an experimental technique used in the determination of large molecular assemblies. The mmCIF dictionary extensions developed for cryo-electron microscopy (MSD-EBI and RCSB, 2000) include a description of sample preparation, raw volume data (Henrick *et al*., 2003), structure solution, and refinement.

3.6. Protein production

The detailed recommendations of a Task Force of the International Structural Genomics Organization (ISGO) (International Structural Genomics Organization, 2003) provide the foundation for a set of mmCIF dictionary extensions describing protein production. Data items describing protein expression, cloning, purification, NMR screening, and crystallization are included in this extension dictionary. These data extensions have been used as the foundation for the Protein Expression Purification and Crystallization database (RCSB, 2004) and for the protein production

process model developed to support the Structural Proteomics in Europe initiative (SPINE, 2004).

3.7. Protein structure classification

Taxonomies describing common protein shape are important for understanding protein function and evolutionary relationships. The Structural Classification of Proteins (SCOP) database (Murzin *et al*., 1995) has developed a structural taxonomy created by manual inspection and automated methods based on evolutionary-related families, superfamilies, and folds. Another taxonomy, CATH (Orengo *et al*., 1999), is a novel hierarchical classification of protein domain structures, which clusters proteins at four major levels, Class (C), Architecture (A), Topology (T), and Homologous superfamily (H).

3.8. RNAML

RNAML (Waugh *et al*., 2002) is an XML representation of RNA sequence and structural features. This representation was developed within the RNA community to provide a standard means of exchanging information about RNA. The Nucleic Acid Database (NDB) (Berman *et al*., 1992) distributes these data files for known RNA structures. Software tools that use RNAML to compute and display RNA secondary and tertiary structure are also available (Yang *et al*., 2003).

3.9. Homology models

Homology models provide important computational insights into understanding 3 D macromolecular structure. An mmCIF extension dictionary describing methodology and outcomes of homology models has been developed (Adzhubei and Migliavacca, 1999). The details of template selection, template alignment, minimization or molecular dynamics treatments, and model quality assessments are included in this dictionary extension.

Short Specialist Review

MAGE-OM: An object model for the communication of microarray data

Catherine A. Ball
Stanford University School of Medicine, Department of Biochemistry, Stanford, CA, US

Paul T. Spellman
Lawrence Berkeley National Laboratory, Life Sciences Division, Berkeley, CA, US

Michael Miller
Rosetta Inpharmatics, Seattle, WA, US

1. Background

All attempts to take advantage of the data being generated by large-scale biomedical technologies share two major challenges. First, the scale of data being produced requires computational infrastructure that is often immature and in the process of being built. Second, the considerable investment required to generate large-scale datasets necessitates additional measures to preserve and disseminate date for uses other than the primary experiment. These issues are very much intertwined: computational access to such data helps preserve and disseminate them, although providing the data in a format that is computer-friendly requires special measures that are often beyond the scope of the project that generates the data. Data storage for a single project can usually be provided in a reasonably straightforward manner, but sharing data with collaborators, sending data to repositories, exporting data to software packages, and providing data in a format that can be adequately reanalyzed by others can provide nearly insurmountable challenges. In addition, it is crucial to adequately express the biological context for the experiments or the data are meaningless. Agreeing which details are crucial, what to call those details and the format in which to communicate those details are easily overlooked, often ignored, and unspeakably dull, but is nonetheless critical. Without a format that is predictable and adequately structured, it is impossible to communicate large-scale datasets to others without loss of information.

Microarray experiments are one example of large-scale biological technologies that are being widely used by biomedical researchers. The amount of data

being produced usually exceeds the abilities of the laboratories generating the data. When microarrays were new technology, no standards existed to specify which critical details were needed to preserve the value of the data and no data formats existed with which to exchange data with others. In 1999, the grassroots Microarray Gene Expression Data Society (MGED; **www.mged.org**) was formed to construct such standards. The Minimum Information Annotating a Microarray Experiment (MIAME, Brazma *et al*., 2001) specifies which types of data and annotation ought to be communicated for a microarray study to stand on its own. Later, it was proposed that the MicroArray Gene Expression Markup Language (MAGE-ML) be used to communicate data (Spellman *et al*., 2002). Like MIAME, MAGE was created by the collaboration of individuals at public, academic, and corporate institutions who were united by the need for a common format to promote sharing of microarray data. When complete, the European Bioinformatics Institute and Rosetta Inpharmatics, Limited Liability Company (LLC), in a collaboration between nonprofit and industry, brought MAGE before the Object Management Group where it became the Gene Expression Standard.

The term 'MAGE' refers to a collection of related specifications and technologies that make it possible to encode MIAME-compliant data describing experiments using microarray technology. The Microarray Gene Expression Object Model (MAGE-OM) is a UML (Unified Modeling Language) object model to assist in the conceptualization and representation of a microarray investigation, while MAGE-ML is an XML- (EXtensible Markup Language) based implementation of MAGE-OM. MAGE-OM contains 132 classes that are organized into 17 packages. Classes in MAGE-OM represent discrete things or events associated with a microarray experiment because packages group related objects together. For example, the *BioSequence* package contains six classes that describe a given biological sequence, its features, its relationships to other biological sequences and its location, and use in individual microarrays. Importantly, the MAGE object model closely follows the flow of a microarray investigation and is thereby able to capture the core requirements for MIAME compliance. MAGE provides ways to describe an experiment's goals and design, the biological materials manipulated and used in the execution of an experiment, the design and manufacture of microarrays, the protocols used in the course of a microarray experiment, and the resulting data generated from a microarray experiment.

MAGE relies on external ontologies to provide concrete and specific details that are beyond the scope of the MAGE-OM. For example, the National Center for Biotechnology Information taxonomy (Wheeler *et al*., 2000; Benson *et al*., 2000) can be referenced to describe the species from which DNA sequences on an array (DesignElements in the MAGE-OM) are generated. One could also use the Jackson Laboratories mouse anatomy ontology (Begley and Ringwald, 2002; Ringwald *et al*., 2001) to describe an experiment where gene expression differences between mouse tissues were identified. The MGED Ontology (**http://mged.sourceforge.net/ontologies/MGEDontology.php**) encodes

many MIAME ideas and is one of the first biological ontologies to provide annotations that describe general experimental details.

2. Who is using MAGE?

Several commercial microarray vendors (e.g., Agilent and Affymetrix) provide descriptions of their microarrays using MAGE-ML. The MAGE-ML files are used by experimenters' research software applications and by microarray data repositories (such as ArrayExpress (Parkinson *et al.*, 2005) and the Gene Expression Omnibus (GEO, Barrett *et al.*, 2005)) to identify the biological reporters associated with each microarray spot. In addition, many microarray research databases (e.g., Stanford Microarray Database (SMD, Ball *et al.*, 2005), BioArray Software Environment (BASE, Saal *et al.*, 2002), RNA Abundance Database (RAD, Manduchi *et al.*, 2004), Microarrray Data Manager (MADAM Saeed *et al.*, 2003)) and software packages used by experimenters for the prepublication analysis of microarray data have MAGE-ML export ability. This allows researchers to submit MAGE-ML records of their published experiments directly to ArrayExpress or GEO without loss of information. The number of software applications and microarray vendors using MAGE increases every year, as community demand for more seamless data sharing increases.

3. MAGEstk

MAGEstk (pronounced "majestic") is the MAGE software toolkit that provides code for Java, Perl, and C++ programmers. It is freely available at **http://mged.sourceforge.net/** and is an open source based on the Massachusetts Institute of Technology license. This toolkit, actively developed by contributors all over the world, is targeted to bioinformaticians, database and application programmers, and groups or individuals who use microarrays. MAGEstk provides many basic functionalities for creating and handling MAGE files and using the MGED ontology. MAGEstk, like MAGE, is a product of the bioinformatics community and regular programming jamborees (usually twice a year) are held during which software developers contribute their time and expertise to writing new tools for MAGEstk. The first component of MAGEstk is the UML compiler that produces the second component – MAGE-ML parsers and writers. The third component is a MAGE-ML validator that ensures that individual or sets of documents conform to critical rules.

The MAGEstk parsers process MAGE-ML into in-memory object structures (either Perl or Java) and, conversely, serialize object structures to MAGE-ML. Both sets of modules are available for use from SourceForge. These modules allow a consistent application programming interface (API) based on the names of the objects in the model and the names of the associations between objects. The Perl and Java modules for MAGE-ML parsing are generated almost entirely using a set of rule-based mappings that allow automatic code production, with only a few hand-coded

exceptions from the UML MAGE-OM model. The MAGE validator tool is freely available from **ftp://ftp.ebi.ac.uk/pub/databases/arrayexpress/MAGEvalidator-DISTRIB/**. The tool has been written in Java and can be installed locally on Windows or Unix platforms. The tool reads a MAGE-ML file, checks its validity based on criteria such as the nonduplication of object identifiers and the presence of required MIAME fields, and produces the validation log (for more see **http://www.ebi.ac.uk/∼ele/ext/submitter.html#val**).

4. Barriers to using MAGE

Unless an experimenter has access to one of the research databases or software packages that read MAGE-ML and automate MAGE-ML generation, there are significant hurdles to using MAGE. Using the MAGE-OM still requires a high level of programming expertise and familiarity with the object model that, unfortunately, is beyond the abilities of the average bench biologist. Although the MAGEstk provides a certain level of common tools and approaches, any given project is likely to have to write some programming code in order to import or export MAGE-ML files. This is increasingly mitigated by a growth in the number of laboratories with informatics resources as well as the bioinformatics community's embrace of open software. Many high-quality software packages are freely available that are able to produce microarray data in MAGE-ML.

Importing MAGE-ML files produced by others presents additional challenges because there are occasional redundancies in the object model that allow different applications to record the same information in different places in the object model. This ambiguity leads to some difficulties using MAGE-ML from different sources. However, this can usually be addressed with communication, and resolving this difficulty is a major goal in the next version of MAGE (see Section (5) below). A more obstinate problem is that MAGE-ML files are very large, making reading by humans essentially impossible. Keeping in mind that some commercial microarrays have more than a million features whose sequences and biological identity must be recorded, it is clear that the amount of data associated with microarray experiments is by definition large, and the structure of XML results in a very significant increase in file size. Methods to handle these large files are available in the MAGEstk software toolkit, but simply storing, moving or processing such large files provides challenges.

5. Future plans

MAGE developers are now embarking on two new projects. The first is to develop and disseminate a second version of MAGE-OM (MAGE-OM v2) that will require less interpretation than the current version. The second goal is to incorporate MAGE into a greater object model for a superset of large-scale biomedical technologies, called Functional Genomics (FuGE).

MAGE-OM v2 will address five areas that are currently recognized as limiting. The first is that MAGE-OM is difficult to extend to other high-throughput

technologies. This goal is tied in closely with our efforts with FuGE. Second, the model structure needs to be simplified so that it is easier to use – in some cases there are unnecessary levels of detail that is difficult to interpret and apply correctly. Third, ambiguities in the model need to be eliminated so that MAGE-ML documents can be more easily interpreted by different software packages. The fourth task is to completely incorporate the MGED Ontology (which did not exist when MAGE-OM was first developed). Lastly, the model needs to be expanded to fully specify higher-level data analysis procedures and quality assessment measurements.

The goal of FuGE is to share resources between different large-scale data generating groups for similar types of objects (such as descriptions of experimental procedures, biological samples or clinical data) and to have specialized objects be designed by those with expertise in the domain (such as proteomics). In this manner, bioinformaticists will not have to reinvent the wheel for every high-throughput technology that is being applied to biomedical questions. The only new modeling required will be that needed to record technology-specific details.

MAGE development will continue to be a community-driven project. Our experience has taught us that those most closely involved in generating, storing, and analyzing microarray data have the most to gain by the development of resources and software such as MAGE-OM and MAGEstk. Conversely, those same bioinformaticians have the most to lose by having standards foisted upon them that are unwieldy and of little practical value. Accordingly, community involvement and contributions to MAGE-OM and MAGEstk have been remarkable. A far-flung group from many sectors of the biomedical and bioinformatics research communities helped to create MAGE-OM, to contribute code to MAGEstk, and to provide the constructive criticism needed to pinpoint the areas for future research. Without the active participation of individuals from many organizations, there would be no MAGE-OM and no hope of releasing an improved second version.

Frame-based systems: Protégé

Iwei Yeh
Stanford University, Stanford, CA, USA

A conceptualization is an abstract, simplified view of a domain of interest (Gruber, 1993). Concepts represent classes of objects in a domain. For example, the concept gene represents the set of genes that occur in nature. These concepts have describable attributes to them, such as the name of a particular gene, as well as relationships between them, such as the relationship between a gene and its protein product. These attributes and relationships define a class of objects in the real world, and their values define the individuals. An ontology is a formal specification of a conceptualization. Well-structured ontologies allow querying of complex relationships within large data sets and facilitate automatic inference of new knowledge (Russell and Norvig, 1995; Bada and Altman, 2000). Modeling data sources to closely reflect the reality of the world they are trying to describe is the key to general reusability and intuitive querying.

An important method for representing ontologies is one that is based on frames (Fikes and Kehler, 1985; Minsky, 1987; Karp, 1992). Minsky popularized the frame as a data structure by drawing an analogy with the mental structures people use when dealing with stereotyped situations. Minsky argued that people use "frames", which can be used to represent generic concepts, such as a birthday party, and these concepts have specific characteristics, such as the number of people attending or the kind of birthday cake. These characteristics of a frame may have default values but can be filled in for the specific occasion (for example, the cake is always chocolate unless otherwise specified). In frame-based systems, a class frame represents each concept and contains slots describing its attributes. Facets describe properties of slots, such as their allowed values and cardinality. A relation is an attribute that has another frame as the allowed value type. An instance frame is one that represents a particular object from the set of objects described by the class; it is a copy of the class frame with default values with slot values filled in for the particular instance.

A special relation is the *is-a* relation that organizes frames into a taxonomic hierarchy and allows for inheritance of slot values. Inheritance allows subconcepts (classes or instances) to inherit the parent concept's slot values, decreasing redundancy of stored information, thereby reducing the chance of inconsistencies and increasing the efficiency of updates.

Frames are conceptually simple and easy to understand, and the information in frames is directly stored or easy to compute via *is-a* relationships. A disadvantage of frames is that they provide a static representation, where each *is-a* relation must be

asserted and cannot be inferred by the system (Baker *et al*., 1999). The meaning of the different relations must be carefully defined so that the semantics of the relation are clear and not misinterpreted. Even for the basic *is-a* link, there are many possible interpretations that must be distinguished (Brachman, 1983). Flier *et al*. describe three types of *is-a* relationships: "A is by definition B", "A is probably a B", and "A is in theory necessarily a B" (Flier and Zanstra, 1998). Each frame is viewed as an assertion, or statement of fact. Therefore, expression of incomplete knowledge in a frame-based system can be very difficult (Brachman *et al*., 1987). For example, it is difficult to state that the slot of a specific instance is one of two out of many possible values. Querying in frame-based systems consists of following *is-a* links for determining subsumption and other links for other types of inference.

A knowledge base (KB) is an ontology with the addition of instances. A knowledge base management system (KBMS) facilitates knowledge modeling, knowledge acquisition, consistency checking, and concurrency control of ontologies and KBs. *Knowledge modeling* is the creation of classes, slots (with default values), and facets. *Knowledge acquisition* involves extracting knowledge about the domain from various sources. *Consistency checking* ensures that classes and instances in the KB have attributes that conform to the knowledge model. *Concurrency control* maintains appropriate behavior of the KB during and after simultaneous operations.

Protégé is an open-source KBMS environment (Gennari *et al*., 2003), which is written in Java and available for several platforms (**http://protege.stanford.edu**). Protégé is based on frames and conforms to the OKBC interface (**http://www.ksl.stanford.edu/software/OKBC/**), which integrates KBs across systems. Many biological ontologies are available in Protégé format, including a biological processes ontology, anatomy ontology, and Gene Ontology (Hahn *et al*., 1999; Peleg *et al*., 2002; Yeh *et al*., 2003). Ontologies in Protégé are easily sharable due to the availability of the software, and the various formats of storing the ontology (including text and database formats). Protégé provides a graphical user interface for creating and editing ontologies and KBs.

In Figure 1, the classes tab of Protégé is activated, and the *is-a* hierarchy for a cellular architecture ontology is shown in the pane at the left (unpublished work). The concept *endosome membrane* is highlighted, and the attributes of the frame representing the concept are shown in the pane on the right. Template Slots are attributes that apply to the instances of endosome membrane, while the other attributes are for the concept or class itself. The hierarchy is clickable, and children concepts can be either hidden or shown.

Protégé assists in the task of knowledge acquisition by automatically generating forms for creating instances based on class definitions. The instance tab is shown in Figure 2.

This allows the tasks of knowledge modeling and knowledge acquisition to be easily separated between users. The automatically generated form enforces the constraints of attribute type and cardinality that are defined during class creation. Users can easily browse instances through the class hierarchy in the left pane.

There have been several tools developed within the Protégé framework to assist users in developing, maintaining, and querying KBs (**http://protege.stanford.edu/plugins.html**). The queries tab allows users to search for instances based on class and slot values. For more complex queries and constraints, the Protégé Axiom

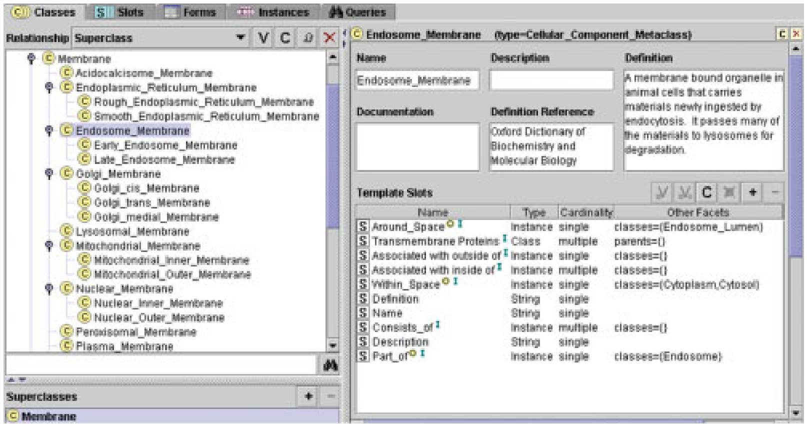

Figure 1 Screenshot of Protégé with classes tab activated, and the class Endosome Membrane highlighted in the pane on the right

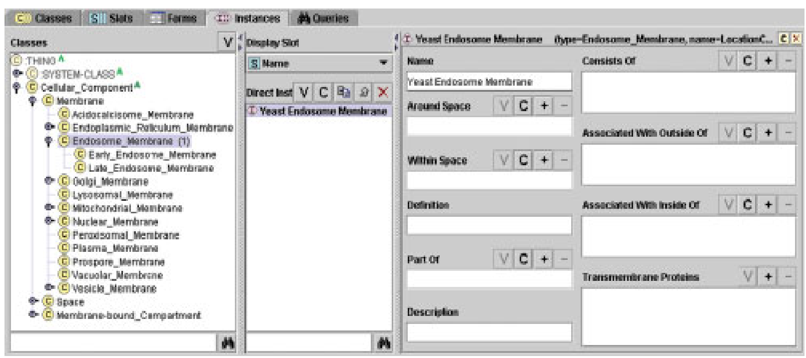

Figure 2 Screenshot of Protégé with instances tab activated. The class Endosome Membrane is highlighted in the classes pane on the far left. The central pane shows the instances of Endosome Membrane and the Yeast Endosome Membrane is highlighted. At the pane on the far right, a user can edit slot values for this instance

Language (PAL), which uses a superset of first-order logic, allows users to logically query and create constraints over a KB based on classes, instances, and their attributes. PROMPT is a suite of tools for managing multiple ontologies, and automatically generates a list of differences and similarities between two input ontologies (Noy and Musen, in press). This allows users to develop the same ontology in parallel and integrate changes at a later time. Protégé has also been extended to enable usage of non-frame-based representations, including XML schema, and OWL (*see* Article 92, **Description logics: OWL and DAML + OIL**, Volume 8) (Gennari *et al*., 2001; Rector, 2004). This allows for import and export of Protégé projects to and from other systems and integration of Protégé projects with ontologies generated in other platforms.

These additional tools developed for Protégé were created using the Protégé Java API. The API is well documented (**http://protege.stanford.edu/doc/pdk/index.**

html) and allows users to develop plug-in extensions for Protégé-2000 or separate programs that interface with Protégé projects. This allows for more individualized and sophisticated querying algorithms as well as automatic KB population from high-throughput data sources.

Basic Techniques and Approaches

Description logics: OWL and DAML + OIL

Phillip Lord, Robert D. Stevens, Carole A. Goble and Ian Horrocks
University of Manchester, Manchester, UK

OWL and its predecessor, DAML + OIL, are ontology languages developed for the *Semantic Web*. As such, they support its aim of increasing the amount of information on the web that is computationally accessible (i.e., that can be unambiguously interpreted and processed by software as well as humans). With the acceptance of OWL as a recommendation by the W3C (World Wide Web Consortium, the standards body for web technologies), this language is moving from research into mainstream technology with increasing use and availability of tools such as the editors Protégé (*see* Article 91, **Frame-based systems: Protégé**, Volume 8) and OilEd. Underlying a fragment of OWL called *OWL-DL* is a Description Logic (DL), which supports the definition and description of concepts, relationships, individuals and axioms (constraints), and the organization of concepts and relationships into hierarchies.

Description Logics have several key features that make them attractive as ontology languages:

Expressivity: DLs are highly expressive, enabling rich, and complex descriptions of domain concepts. Concepts can be defined in terms of their properties and their relationships to other concepts. It is not necessary to use all of the expressive power in OWL, however. Some or all of the ontology can be represented as a simple taxonomy.

Automated Reasoning: DLs are logics which means there is a clear understanding of the language's formal properties. This has enabled the development of reasoners – software that is capable of checking ontologies for consistency and inferring that one concept is a kind of another concept. This latter characteristic means that the concept hierarchy can be inferred on the basis of the contents of the ontology instead of being handcrafted by the ontologist.

Compositionality: The previous two properties enable the building of ontologies in a compositional way – making new concepts by combining previously defined concepts and properties. This means that it is unnecessary to predetermine and enumerate all the concepts of the ontology beforehand, making the process of building large ontologies more manageable and flexible.

```
Protein that is associated with chromosomal DNA, including
histones, protamines, and high-mobility group proteins
```

Statement 1 Chromosomal Protein: as defined by Swissprot

```
ObjectProperty(isPartOf)
Class(Protein)
Class(Chromosome)
Class(ChromosomalProtein partial
    Protein
    restriction(isPartOf someValuesFrom(Chromosome)))
```

Statement 2 Chromosomal Protein: These statements define a property "isPartOf" and two classes, Protein and Chromosome. The third class, ChromosomalProtein, is defined as a subclass of protein and a part of chromosome. The syntax used here is a slight variation on the OWL Abstract Syntax, which is described at **http://www.w3.org/TR/owl-semantics/**

DLs differ from frame-based ontology languages (*see* Article 91, **Frame-based systems: Protégé**, Volume 8) primarily because of their amenability to automated reasoning. They share a common heritage, however, having evolved from early frame-based systems, but with the addition of a more formally defined semantics.

To illustrate the features of DLs, we show how OWL might be used to describe aspects of chromosome biology. In particular, we aim to show how automated reasoning can help in the construction of these descriptions.

Statement 1 shows Swissprot's definition of the Chromosomal Protein keyword – part of a controlled vocabulary, which avoids problems of synonyms and context. The definition of this term is in English and is therefore not accessible computationally, which leaves no explicit statement of the relationship between this and other similar keywords. The Gene Ontology (*see* Article 82, **The Gene Ontology project**, Volume 8) also recognizes this difficulty and provides a means for defining relationships between concepts.

DL systems not only support but also encourage the definition of relationships between different concepts. So in Statement 2, "chromosomal protein" is defined in terms of "chromosome" and "protein".

Two different kinds of relationship have been used: the subclass, or subsumption, relationship, and isPartOf. OWL enables the definition of new properties, which can then be used in descriptions. OWL properties can themselves have characteristics. So isPartOf might be defined as the inverse of hasPart. In Statement 3, we provide definitions for Chromosome and SegregatingUnit. As well as defining a new property (involvedIn), some of the more expressive features of OWL are used.

DLs are logics and as such have *well-defined* semantics, which enables a precise machine interpretation of the definitions of concepts in an ontology. The most important practical outcome of this has been the development of DL reasoners – software components that are capable of determining the *satisfiability* of ontological concepts. For example, the descriptions in Statement 4 state that an AcentricChromosome is a Chromosome and that it has no Centromere. A DL reasoner will discover that this concept is *unsatisfiable* – the definition is contradictory. In this

```
ObjectProperty(involvedIn)
ObjectProperty(hasPart)

Class(SegregatingUnit complete
    restriction(involvedIn someValuesFrom (Segregation)))
Class(Chromosome complete
    intersectionOf(SegregatingUnit
        restriction(hasPart someValuesFrom (Telomere))
        restriction(hasPart someValuesFrom (Centromere))))
```

Statement 3 Chromosome: Two more properties and two more classes are defined. These class descriptions are "complete" (that is, the definition is equivalent to the class and vice versa) rather than "partial"; all Segregating Units are involved in Segregation, *and* anything involved in Segregation is a Segregating Unit. A Chromosome is defined as a Segregating Unit with a telomere and a centromere

```
Class(AcentricChromosome partial Chromosome)
DisjointClasses(restriction(hasPart someValuesFrom (Centromere))
   AcentricChromosome)
```

Statement 4 Acentric Chromsome: Here, an acentric chromosome is defined. It is also described as "disjoint" from "things having a part centromere", or there can be nothing that both has a centromere and be an acentric chromsome

case, a Chromosome is described as having a Centromere, so either an Acentric-Chromosome must have a Centromere or not be a Chromosome.

The biologist may agree or disagree as to whether an acentric chromosome is really a chromosome or not. DLs can give no guarantee that the ontology being produced is a good model of reality or otherwise. However, the reasoner can at least check that the model is internally consistent. The ontology developer is forced to consider which one of their definitions should be modeled differently. We can draw an analogy to a type system in a programming language in that the explicit definitions enable errors to be picked up and resolved earlier in the process.

In addition to satisfiability, DL reasoners are capable of determining *subsumption* relationships between concepts based on their descriptions. We might choose to define YAC (Yeast Artificial Chromosome) as shown in Statement 5. In this case, the DL reasoner is capable of telling us that a YAC as well as being a CloningVector is also a kind of Chromosome; a YAC is a SegregatingUnit with a Telomere and a Centromere that Statement 3 defines to be equivalent to a Chromosome.

```
Class(CloningVector partial
    SegregatingUnit)

Class(YAC partial CloningVector
   restriction(hasPart someValuesFrom (Telomere))
   restriction(hasPart someValuesFrom (Centromere)))
```

Statement 5 Yeast Artifical Chromosome: A cloning vector with a telomere and a centromere as part. A Cloning Vector is defined as a kind of SegregatingUnit

The use of automated reasoning technologies also enables the ontological engineer to adopt a different style of modeling, one which is highly compositional. Enabling the definition of concepts in terms of their properties reduces the task of building a large hierarchy of concepts to that of building a set of much smaller hierarchies over which the reasoner can operate. In practice, this can enable the generation of large, internally consistent ontologies (*see* Article 85, **TAMBIS: transparent access to multiple bioinformatics services**, Volume 8).

Statement 5 gives an example. The ontology developer need not consider the subsumption relationship between a chromosome and a YAC as the reasoner is capable of determining this. Nor need they worry about the order of definition of concepts. If YAC is defined first and at a later date the ontologist adds a definition for Chromosome, the reasoner will ensure that this concept has all appropriate subclasses including YAC.

In Conclusion, Description Logics and OWL offer the ontology builder a rich and expressive formalism for expressing concepts in terms of their properties. The provision of a formal semantics for the language ensures that the definitions of these concepts are computationally amenable, which in turn facilitates the building of large ontologies. Bioinformatics as a discipline has historically been an earlier adopter and contributor to web technologies. Hopefully, the advent of the widespread use of ontologies in bioinformatics in the shape of the Gene Ontology and arrival of Semantic Web technologies such as OWL will continue this trend.

Introductory Review

Detecting protein homology using NCBI tools

Wayne T. Matten and Scott D. McGinnis

National Center for Biotechnology Information, Bethesda, MD, USA

1. Introduction

Scientists around the world use a public web page to submit more than 100 000 sequence searches a day to the National Center for Biotechnology Information (NCBI). The NCBI computers run a program called *BLAST*® (Basic Local Alignment Search Tool), which provides an indication of how similar the query sequence is to other known sequences (Altschul *et al*., 1997). What drives this craving for sequence similarity? Common uses are as follows:

- To infer homology. Two sequences from different species are said to be homologous when they are derived from a common ancestor sequence. Sequence similarity provides a measure of this relatedness.
- To infer function. The potential function of a poorly characterized protein can be assigned on the basis of its sequence, and possibly structural, similarity to well-studied proteins in other organisms. This often includes identification of known conserved domains in the protein (*see* Article 91, **Classification of proteins by sequence signatures**, Volume 6).
- To identify unknown sequences, such as newly sequenced DNA, or peptide fragments from high-throughput studies of protein mixtures (*see* Article 17, **Tutorial on tandem mass spectrometry database searching**, Volume 5).
- To study evolution by following changes in protein homologs and protein families over time (*see* Article 9, **Modeling protein evolution**, Volume 1).

This review focuses on protein sequence comparison, which is more sensitive – can detect similarity in more evolutionarily distant organisms – than nucleotide sequence comparison. One must keep in mind that programs such as BLAST do not calculate homology; they only provide data that may support an inference of homology. These data include percent sequence identity, scores to help rank the comparisons, statistics to help judge relevance, and the alignments themselves. A common error is to equate the percent identity between two sequences with the degree of homology; two sequences are either homologous or not; they cannot share low or high degrees of homology. Furthermore, BLAST and other popular

Global alignment

Figure 1 Global alignment programs are constrained to find the best match along the full length of the sequences. Here, the Align program (Lipman and Pearson, 1985) was used to compare the *Danio rerio* “similar to cortactin” protein (cort; NCBI Reference Sequence, accession number NP_957335.1; 206 amino acids) and the *Mus musculus* SH3 (src homology 3) domain protein 3 (SH3; NCBI Reference Sequence, accession number NP_059071.1; 215 amino acids). Local alignment programs seek the best *segments* of alignment. The 48 amino acid region found by pairwise BLAST (Tatusova and Madden, 1999) corresponds to the SH3 domain of each protein, highlighted in the global alignment and shown as the thick line in the graphic

tools, such as FASTA (Pearson and Lipman, 1988), generate *local* rather than global alignments, so the percent identity only refers to the aligned regions of the sequences. These local regions of similarity are useful because they often represent conserved domains (Figure 1).

It is easy to understand that the more similar two sequences are, the more likely they are to be related, but at what percent identity overall are two sequences considered homologous? There is no magic degree of similarity that defines homology. Other helpful information includes potential biological function, comparison of many similar sequences (multiple sequence alignment), and the statistics of sequence similarity algorithms.

To help interpret BLAST results, a statistical value called the *Expect value* is calculated for each alignment. The Expect value indicates the number of hits (sequences) in the database searched that are expected to align to the query simply by chance. So an Expect value of 1 means that this alignment could have occurred by chance, that is, may not be biologically meaningful. As the Expect value decreases, the likelihood that the two sequences are related increases (Altschul, 1998).

This review outlines just a few of the possibilities for analyzing protein homology using tools found on the NCBI web site. By design, BLAST trades a bit of sensitivity for the speed that is needed to search large databases via a public search interface. In some cases, more sensitive searches can be performed with algorithms such as Smith–Waterman (Smith and Waterman, 1981) and others (Persson, 2000; Sansom, 2000).

2. Finding homologous sequences

Any search for homologs is dependent both on the sequence comparison program and the database. A very brief review of NCBI's protein databases follows (see also Wheeler *et al*., 2004).

2.1. Entrez protein database

The majority of sequences in NCBI's protein databases are translated coding regions from nucleotide submissions to GenBank, with the exception that high-throughput nucleotide sequences, such as Expressed Sequence Tags (ESTs), are not translated. Text-based access to these records is through Entrez Protein, which includes sequences submitted to outside sources: SWISSPROT, Protein Information Resource (PIR), Protein Research Foundation (PRF), and Protein Data Bank (PDB); the latter contains sequences from solved structures (*see* Article 71, **The Protein Data Bank (PDB) and the Worldwide PDB http://www.wwpdb.org**, Volume 7). Sequence-based access, via a BLAST search against the default protein database nr (nonredundant), includes all of these sequences, except for the Patent division of GenBank.

2.2. Conserved domain database

NCBI's Conserved Domain Database (CDD) contains known, conserved regions of sequence that are represented as position-specific scoring matrices (Marchler-Bauer *et al*., 2003). You can think of domains as modules of function, and often three-dimensional (3D) structures, that are maintained during evolution. CDD's primary use is to identify such domains in a protein sequence to help infer protein function or to place a sequence in a known protein family.

NCBI compiles CDD from both outside databases – Pfam (Bateman *et al*., 2002) and SMART (Letunic *et al*., 2002) – and internal sources, including the database

COGs (Clusters of orthologous groups); (Tatusov *et al*., 2001). A related search tool, CDART, the Conserved Domain Architecture Retrieval Tool, is used to find proteins with a similar set of domains to the query protein (Geer *et al*., 2002).

2.3. BLAST implementations

All of the different BLAST programs can be accessed from the main BLAST web page (**http://www.ncbi.nlm.nih.gov/BLAST/**). This page also provides links to the downloadable BLAST executables, databases, and documentation, **ftp://ftp.ncbi.nlm.nih.gov/blast/**, and to the source code, **ftp://ftp.ncbi.nlm.nih.gov/toolbox/ncbi_tools/ncbi.tar.gz**.

2.4. BLASTP

A BLASTP search against the nr (protein) database is a comprehensive search and often yields satisfactory results. The default scoring matrix, BLOSUM62, is remarkably nimble when comparing sequences from either closely or distantly related species (Henikoff and Henikoff, 1992). However, a good principle in homology searching is to use more than one approach. To be exhaustive, try different scoring matrices, databases, search parameters, and even algorithms.

One common use of BLASTP is to find matches to a short amino acid motif, say, 10–20 residues. A separate BLAST web page called *Search for short, nearly exact matches* tailors the search parameters to the use of short peptide queries: PAM30 scoring matrix (Dayhoff *et al*., 1978); minimum word size; no query filter for low-complexity sequence (Wootton and Federhen, 1993); and increased Expect value cutoff. The Expect value needs to be increased from the default value of 10 because matches greater, that is, worse, than the Expect threshold are not reported and Expect values in the 1000's are frequent with these short query sequences. Note that because of the nature of the BLAST algorithm and the PAM30 scoring matrix, only nearly exact matches to the query will be found. If a motif with ambiguous residues is sought, then a pattern-matching algorithm, not BLAST, is a better choice (Mulder and Apweiler, 2001).

2.5. PSI-BLAST

Position-specific-iterated BLAST (PSI-BLAST) is more sensitive than BLASTP. Greater sensitivity is achieved by constructing a position-specific scoring matrix, referred to as a *PSSM* or profile, from a multiple sequence alignment of the results of a standard BLASTP search. One axis of a PSSM is the aligned region of the query sequence, while the other axis is made up of the standard amino acids (Figure 2). The position-*independent* scoring matrices, such as BLOSUM62 or PAM30, have a defined score for each amino acid substitution, regardless of the residue's position in the query. In effect, a PSSM gives greater weight to those amino acids that are conserved among the sequences in the multiple sequence alignment. By then using the PSSM as the query in subsequent searches or iterations,

Catalytic loop

Figure 2 This incomplete position-specific scoring matrix (PSSM) shows the scores for residues surrounding the catalytic loop of the DAF-1 serine/threonine protein kinase (GenBank accession NP_499868.2), which was used as the query in a command line PSI-BLAST search against the protein nr database. Scores for the lysines (K) in this region range from 7 for the perfectly conserved K448 to 1 for the poorly conserved K435

database sequences that share those conserved residues can achieve higher scores (lower Expect values) than they would with a position-independent scoring matrix.

Optimally, as the PSSM is further refined in each round, the sensitivity increases. Eventually, no new sequences will be found and the search is said to have converged. In most cases, 10 or fewer iterations are sufficient. However, careful choice of the original query sequence is important for a successful search (Aravind and Koonin, 1999).

Another consideration when running PSI-BLAST is where to set a second Expect value threshold, the inclusion threshold. This value, 0.005 by default, determines which of the database sequences to include in the PSSM. The lower this value, the more stringent the selection of sequences for the PSSM. Since this inclusion value is set somewhat arbitrarily, sequences that fall below it – have a higher Expect value – can be manually included in the next PSSM by using a checkbox on the web page.

2.6. PHI-BLAST

Pattern-hit-initiated BLAST (PHI-BLAST) performs a similarity search like BLASTP, but restricts the search to a subset of the database sequences that contain

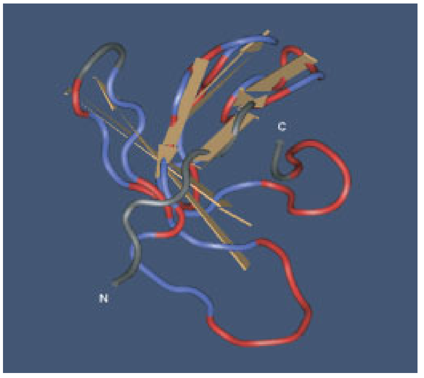
a supplied pattern (Zhang *et al*., 1998). As such, it is not an exhaustive search for all proteins that contain a given pattern; a pattern-matching algorithm might be more useful if that is the objective. The advantage of PHI-BLAST is its incorporation of the BLAST algorithm and associated statistics to enhance the likelihood of finding biologically relevant database sequences and to reduce the number of sequences that contain the pattern simply by chance.

A PHI-BLAST search requires both the pattern, in the syntax of PROSITE (Hulo *et al*., 2004), and a query sequence that contains at least one instance of the pattern. On the PHI-BLAST web page, the results of a PHI-BLAST search are formatted for use in one or more rounds of PSI-BLAST searching.

2.7. Translating BLAST

Protein–protein comparisons using the BLASTP algorithm are also possible when a nucleotide query or database is required. The BLASTX program translates a nucleotide query into all six reading frames – three from the forward DNA strand and three from the reverse – then performs six BLASTP searches against a protein database. TBLASTX similarly translates both the nucleotide query and all sequences in the selected nucleotide database. As you can imagine, TBLASTX absorbs immense computational resources when large nucleotide databases are searched; hence, it is not available on all BLAST pages at NCBI. Finally, the TBLASTN program searches with a protein query against a nucleotide database.

2.8. RPS-BLAST



Reverse position-specific BLAST (RPS-BLAST) is so named because a query sequence is searched against a database made up of PSSMs (recall that in PSI-BLAST a PSSM is searched against a database of sequences). The PSSM database is NCBI's CDD mentioned above. This is the program used to identify known, conserved domains in a query sequence.

3. Finding homologs without running BLAST

In many cases, submitting a BLAST search is unnecessary because NCBI has already done the work for you. As new sequences become available in Entrez, they are compared to all others in the database by BLAST. In other words, it is possible to learn a great deal about a sequence, including identification of homologs, simply by following the links in an Entrez record. The *Related Sequences* link displays a list of precomputed BLAST comparisons sorted from best to worst BLAST score. An analogous link, *BLink* (BLAST link), presents the best 200 hits among the same set of comparisons, but graphically displays the extent of the alignment relative to the full length of the query.

BLink also provides a link to the precomputed RPS-BLAST results (CDD-Search). In Entrez, this link is called *Domains*. Another link, *Domain Relatives*,

Figure 3 BLAST alignment of the solved SH3 domain from human nebulin (1NEB; 60 amino acids) with *Danio rerio* "similar to cortactin" (cort; NP_957335.1; 206 amino acids). The 1NEB structure and the BLAST alignment are color coded by sequence: red = identical residues; gray = no BLAST alignment; arrows denote regions of β-strand. N = amino terminus; C = carboxy terminus

shows the CDART output, immediately revealing other proteins with similar domain architecture.

Another useful link in the BLink output produces the subset of BLAST hits that are in NCBI's structure database, MMDB (Molecular Modeling Database; Chen, 2003). In combination with the structure viewer, Cn3D (Wang *et al*., 2000), you can display the structure for a related protein from the BLink output so that the BLAST alignment – with the original BLink query – is color coded in the Cn3D view. For example, there are currently no structures for a *Danio rerio* SH3 domain. From the BLink output of NP_957335 (Figure 1), you can navigate to the 3D structure of the human nebulin Sh3 domain, and display the BLAST alignment in both the sequence/alignment viewer and the 3D viewer (Figure 3).

4. Homology by structural similarity

Although protein homology has relied heavily on sequence comparison, the underlying assumption is that sequence similarity portends structural similarity, and ultimately, shared function. As more protein structures representing a greater range of protein families are solved, comparisons at the level of 3D structure become more useful (*see* Article 35, **Measuring evolutionary constraints as protein properties reflecting underlying mechanisms**, Volume 7). This is particularly helpful where tools such as BLAST fail to find related proteins because of low sequence similarity (large evolutionary distance). In a general sense, the Vector Alignment Search Tool (VAST) is to structural similarity what BLAST is to sequence similarity (Gibrat

et al., 1996). VAST considers only the secondary structural elements, α-helices and ß-strands, when comparing solved structures, ignoring the sequence. But just as BLAST is used to compute related sequences, new structures entering MMBD get compared to all others by VAST. These precomputed "structure neighbors" are available through links on numerous pages, including the summary page of a structure in MMDB.

Introductory Review

Integrated bioinformatics software at NCBI

Fabrizio Ferre
Boston College, Chestnut Hill, MA, USA

1. Introduction

The NCBI provides several computational resources that can be accessed on-line from **http://www.ncbi.nlm.nih.gov**, or, in many cases, downloaded and installed locally. A recent review of NCBI services and databases can be found in Wheeler (2004). We divided these tools into three categories on the basis of the type of biological data analyzed: nucleotides, proteins, and three-dimensional structure analysis tools. The user is allowed to start from an entire genome, locate regions of interest (through Map Viewer), retrieve a gene or build a transcript using putative exons (by means of Model Maker), and check whether the putative transcript may be translated into a protein (using ORFfinder); orthologs of the gene can be found in the COGs database. UniGene database stores ESTs that can be analyzed by means of ProtEST, while different tissue-specific EST expression levels can be found using DDD. Functional inference of protein functions through three-dimensional structural comparison may be achieved by means of VAST: the user can compare a protein structure with each domain of all currently known three-dimensional protein structures in the MMDB (Molecular Modeling DataBase), thus finding all structural neighbors of the query protein. These neighbors can be used to identify distant homologs whose sequences have diverged to the point that no significant sequence similarity can be detected. Structural superposition can be visualized using the Cn3D software that can be run as a browser plug-in. When comparing proteins, special care should be given to the fact that proteins are modular molecules: the CDD database and the CDD-search tool provide a way to identify the domain composition of a query sequence. Finally, the CDART web tool allows the user to find proteins in the CDD database sharing the same domain architecture of the protein of interest.

2. Nucleotide sequence analysis

2.1. Map viewer

Complete genome maps, from cytogenetic and physical maps down to the sequence level, are accessible for 23 organisms (at the time of this writing) through the Map

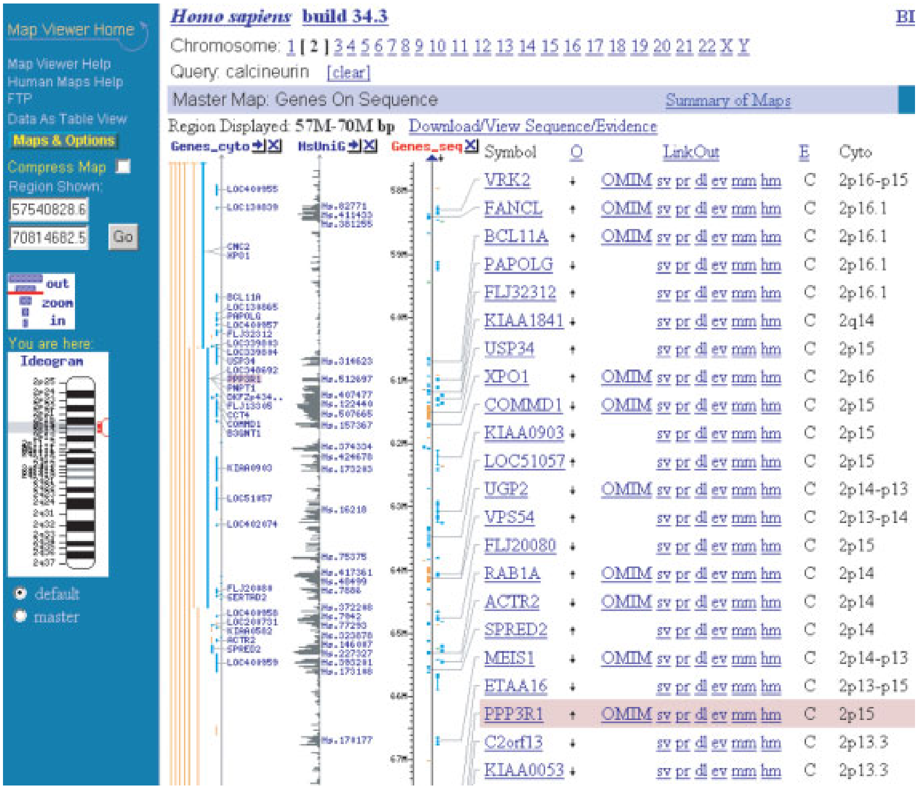

Figure 1 Human calcineurin gene spotted on the chromosome 2 using Map Viewer

Viewer at **http://www.ncbi.nlm.nih.gov/mapview/static/MVstart.html**. The maps can be sequence-based or not (e.g., cytogenetic maps or radiation-hybrid maps). Maps showing gene models, EST, and mRNA alignments used to construct gene models are also available (for some organisms). Different levels of detail allow the user to perform searches (keywords, gene names, SNP identifiers, accession numbers), against an entire genome or a specific chromosome, whose hits are shown on chromosome ideograms (an example can be seen in Figure 1). From this genome view, it is possible to access a map view and zoom into progressively more detailed views. Maps are linked to several resources, such as UniGene clusters, LocusLink, Evidence Viewer, and Model Maker.

2.2. *Model maker*

Model Maker can be used for the construction of transcript models by the assembly of putative exons. The available exons may be derived from predictions or from alignments of ESTs or mRNAs to the genomic sequence. Once the transcript is created, potential ORFs (open reading frames) and their translation are shown. mRNA models can be saved locally for use in other programs. Model Maker is accessible from genomic maps displayed with Map Viewer.

2.3. SAGEmap

SAGEmap (**http://www.ncbi.nlm.nih.gov/SAGE/**) is an on-line resource to store, retrieve, and compare Serial Analysis of Gene Expression (SAGE) gene expression profiles (Lash, 2000). SAGE libraries are derived from the Cancer Genome Anatomy Project (CGAP) as well as from GenBank SAGE tags; moreover, SAGEmap accepts user-submitted libraries. The user can search through SAGEmap submitting a sequence or accessing a UniGene cluster or a specific library. The expression level of the user-defined sequence is shown in different SAGE libraries. Finally, different libraries can be compared.

2.4. UniGene, ProtEST, and DDD

UniGene (**http://www.ncbi.nlm.nih.gov/UniGene**) is a system for the automatic clustering of GenBank sequences and ESTs into nonredundant groups; each cluster represents a unique gene. ESTs (Expressed Sequence Tags) are short (up to 600 bases) DNA subsequences of expressed genes, derived from the automated sequencing of randomly selected cDNA clones. For technical reasons, ESTs are prone to errors. Nonetheless, ESTs are extremely useful for the discovery of new genes and as tags for the identification of which genes are expressed in a given cell type or tissue under specific condition, or in particular phases of the cell cycle. The GenBank database hosts a very large section dedicated to ESTs (dbEST). The UniGene project tries to identify all ESTs generated from the same genes, overcoming problems due to the EST sequence errors. UniGene then stores, for a given organism, tissue, organ or pathological condition, libraries of clustered ESTs. ProtEST is a tool that uses BLASTX (*see* Article 93, **Detecting protein homology using NCBI tools**, Volume 8) to search through sequence databases (Swissprot, PIR, PDB, PRF) with possible translations of UniGene clusters. Proteomes from eight organisms (human, mice, rat, *Drosophila*, *Caenorhabditis elegans*, *Saccharomyces cerevisiae*, *Arabidopsis thaliana*, *Escherichia coli*) are used for the comparison, and the best match in each organism is presented to the user. The UniGene cluster containing the human calcineurin B gene, and an example of ProtEST results, are shown in Figure 2. DDD (Digital Differential Display) is a tool for comparing EST-based expression profiles among different UniGene libraries, with the aim of finding genes related to tissue-specific or organ-specific processes, or related to specific pathologies (identifying genes for which the expression levels differ between normal and disease conditions), or related to different development stages. The user must select at least two pools of libraries, then the software outputs those genes whose expression levels are significantly different between each pair of libraries (computed by means of the Fisher Exact test) among the pools.

2.5. ORFfinder

The ORF (Open Reading Frame) Finder (**http://www.ncbi.nlm.nih.gov/gorf/gorf.html**) is a tool for the identification of all ORFs in a user-submitted sequence or

Figure 2 UniGene cluster containing the human calcineurin gene. In the pop-up panel, the ProtEST search result for the first protein in the UniGene cluster is shown

in a sequence in the GenBank database, by locating stop and start codons in all the reading frames. The user can select the minimum and maximum size of the ORF, and can choose among different genetic codes (standard, mitochondrial, bacterial, ciliate, etc.). If an open reading frame is found, the amino acid translation can be used for similarity search by means of BLAST or in the COGs database.

2.6. Electronic PCR

Sequence Tagged Sites (STS) are defined as pairs of oligonucleotide primers that can be used in a PCR assay to identify unique sites in a genome, and have been extremely useful in the construction of genomic maps. The electronic PCR software (e-PCR; Schuler, 1997; URL: **http://www.ncbi.nlm.nih.gov/sutils/e-pcr/**) looks for potential STSs given a pair of PCR primers and a DNA sequence; the tool looks for DNA subsequences that are closely similar to the primers, and checks if order, orientation, and spacing are correct. e-PCR can be used in two ways: forward (searching a STS database with a sequence) or reverse (searching a sequence database with a STS). The forward mode is useful to map a sequence on a genome using a large database of known STSs (UniSTS). The reverse mode is a recent addition to the web server that is used for the prediction of PCR products in a selected genome given one or more pairs of primers.

2.7. VecScreen

VecScreen (**http://www.ncbi.nlm.nih.gov/VecScreen/VecScreen.html**) is a system for the identification of segments of a nucleic acid sequence that may be the result of a contamination, of vector origin (plasmid, phage, cosmid, YAC DNA) as well as linkers, adapters, and primers. This tool is intended to minimize the incidence and impact of such contaminations in public sequence databases. A specialized nonredundant vector database (UniVec) has been compiled and is used to scan the input sequence. VecScreen performs a BLASTN search using stringent parameters; fragments of vector origin are displayed and classified in four groups (strong, moderate, weak, suspect).

2.8. Spidey

Spidey (**http://www.ncbi.nlm.nih.gov/IEB/Research/Ostell/Spidey/**) is a tool for the alignment of one or more mRNA (FASTA format sequences or accession numbers) on a single eukaryotic genomic sequence, determining the exon/intron structure of the query messenger. This software uses BLAST searches to identify a genome window that covers the entire mRNA length, then refines the alignment to align each exon, taking into account predicted splice sites (four splice-site matrices can be used, i.e., vertebrate, *Drosophila*, *C. elegans*, and plant). The Spidey output is an alignment for each exon, each one evaluated for its quality.

3. Protein sequence analysis

3.1. COG

Orthologs are homologous genes of different species with a common ancestor; finding orthologs is extremely useful for functional predictions in poorly characterized genomes. Tatusov (1997) developed a system to find, cluster, and store

sets of orthologs (Clusters of Orthologous Groups, COGs; URL: **http://www.ncbi.nlm.nih.gov/COG/**). The latest release (Tatusov, 2003) contains information derived from seven complete eukaryotic genomes and 66 prokaryotic genomes. The current eukaryotic section (called KOG) contains 4852 clusters of orthologs, including 54% of known eukaryotic proteins, while the coverage for prokaryotic proteins is higher (around 75%), probably due to higher numbers of analyzed genomes. Each COG consists of individual orthologous proteins (or orthologous sets of paralogs) from three or more genomes. COGs are constructed by means of a mixture of automatic (for finding the orthologs) and manual steps (to split multidomain proteins and to annotate and curate each COG). The integrated COGnitor software allows the comparison of a user-submitted sequence against the database, reporting those COGs to which the input protein may belong. The user can choose the minimum number of organisms represented in the output COGs.

3.2. CDD and CD-Search

The Conserved Domain Database (CDD; Marchler-Bauer, 2003; URL **http://www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml**) is a collection of protein domain multiple alignments; the database has been built using information derived from Pfam (Bateman, 2002) and SMART (Letunic, 2004), whose multiple alignments have been converted into Position Specific Score Matrices (PSSMs), as well as multiple sequence alignments derived from the COG database that are created and curated by NCBI researchers. CDD is linked to the Entrez retrieval system, and the three-dimensional structural alignments can be visualized by means of Cn3D (see in 3D, **http://www.ncbi.nlm.nih.gov/Structure/CN3D/cn3d.shtml**), a free structure and sequence alignment viewer for NCBI databases, available for Windows, Macintosh, and Unix operating systems. CD-Search (**http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi**) is a web tool that allows the identification of protein domain composition of a query sequence. The query submitted by the user is compared to the CDD PSSMs, by means of reverse-position-specific BLAST (RPS-BLAST; Marchler-Bauer, 2002; *see also* Article 93, **Detecting protein homology using NCBI tools**, Volume 8 for details). See Figure 3 for an example. Hits can be displayed as pairwise alignments with a sequence representative of the domain, or as multiple alignments. The Cn3D viewer can be used to visualize the alignments, and a color coding allows the identification the degree of conservation.

3.3. CDART

The Conserved Domain Architecture Retrieval Tool (CDART; Geer, 2002) is a web-based service that performs similarity searches of the NCBI Entrez Protein Database based on domain architecture (i.e., the sequential order of conserved domains). CDART uses a database of domain definitions and annotations based on a nonredundant protein list; RPS-BLAST is used to assign the domain composition to each protein using the domain definitions from the previously described

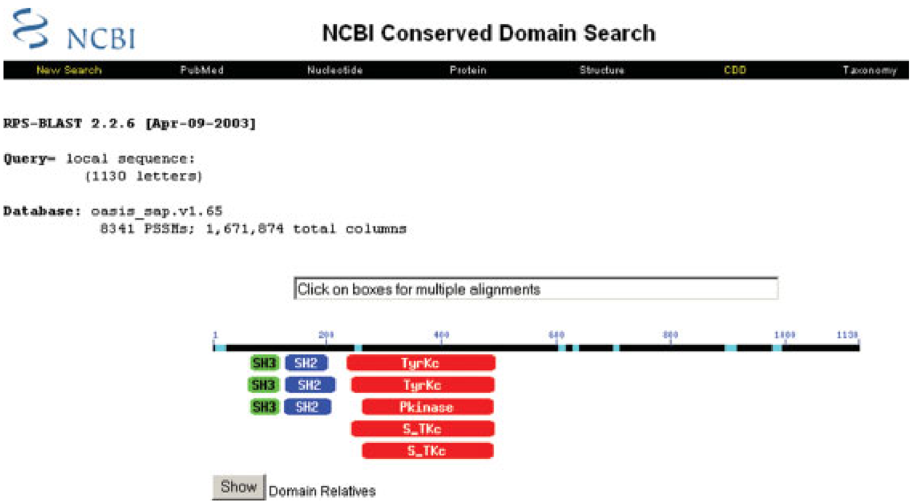

Figure 3 Domains composition of the human C-Abl, determined using CDD-search. Three domains identified (SH3, SH2, kinase catalytic domain)

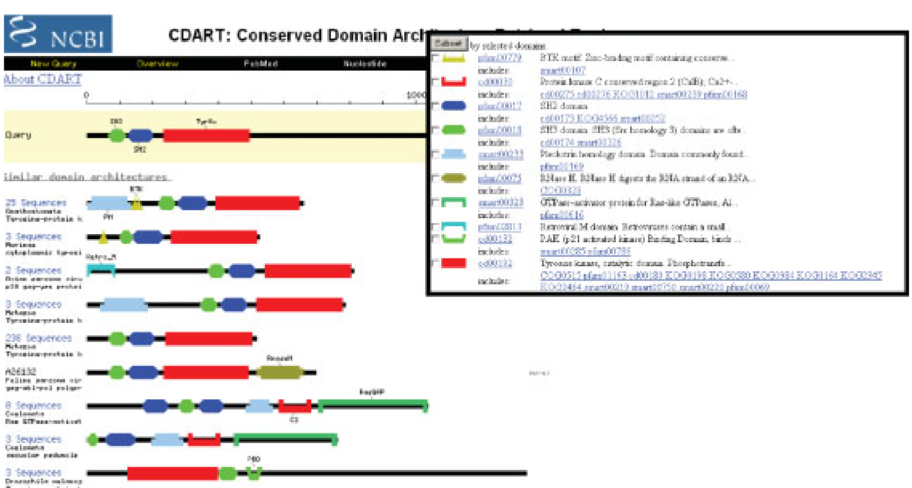

Figure 4 CDART search output. CDART has been used to search for proteins sharing a similar domain architecture as that of the human c-Abl. Each domain is drawn using a different box shape; in the upper right panel the domain legend is shown

CDD (Figure 4). The architectures are recorded in the CDART database along with taxonomic information taken from the NCBI Entrez Taxonomy Database (Wheeler *et al*., 2002). RPS-BLAST is applied to the sequence input by the user, finding domain hits; then, all domain architectures that contain any of the domains in the query are retrieved, and the architectures are compared to that of the query.

CDART is available at **http://www.ncbi.nlm.nih.gov/Structure/lexington/lexington.cgi**.

4. Three-dimensional structure analysis

4.1. VAST

Protein functions are strictly dependent on the three-dimensional arrangement of the amino acid residues; the analysis of protein structures is therefore of crucial relevance in the understanding of the molecular mechanisms of cellular functions. The Vector Alignment Search Tool (VAST; Madej, 1995; Gibrat, 1996) algorithm has been developed to compare protein three-dimensional structures. VAST uses a high-level representation of protein structure as an ensemble of secondary structure elements (SSEs): each SSE is represented as a vector. A seed match of structural similarity is found looking for a pair of SSEs (aligned helices or β-strands) whose type and relative orientation is alike; the similarity search is, for that reason, sequence-independent. Therefore, each comparison requires three steps: (1) from the analysis of the three-dimensional coordinates, the SSEs are identified and converted to linear vectors; (2) the SSEs are optimally aligned looking for statistically significant conserved substructures; finally, (3) a Monte Carlo optimization is applied to refine the conformation of each residue. The residue-by-residue alignment refinement step is applied only to the matches of statistical significance, in order to save computation time by focusing only on those similarities that do not occur by chance. The VAST algorithm has been used to compare all-versus-all protein domains stored in the MMDB database (Chen, 2003). Results of precompiled VAST searches, accessible at **http://www.ncbi.nlm.nih.gov/Structure/VAST/vast.shtml**, are ranked by a similarity measure. This measure may be the VAST score (dependent on the number of superimposed SSEs and on the quality of that superposition; higher scores correlate with higher similarity), the p-value (the probability that the match has occurred by chance) or the rmsd (root mean square deviation, a measure of the distance between two sets of points in space, calculated as the square root of the mean square distances between equivalent C-α atoms). VAST search results may be viewed graphically. For each protein in the database, structural neighbors can be retrieved and superpositions can be visualized by means of Cn3D, which allows simultaneous viewing of both the structural and sequence alignments. Figure 5 shows the structural neighbor for the human c-H-ras p21 protein (PDB/MMDB code 5p21). The user can choose the redundancy level, retrieve the ranked list of neighbors, and then select a subset of matching chains; by clicking on the "View 3D structure" button, Cn3D is launched and the structural superposition is visualized; a lower panel shows the sequence alignment of the selected protein chains.

VAST search (URL **http://www.ncbi.nlm.nih.gov/Structure/VAST/vastsearch.html**) is the web implementation of the VAST algorithm. It can compare the three-dimensional structure of a newly determined protein structure to those in the MMDB database; the user can choose to compare the query structure only to a

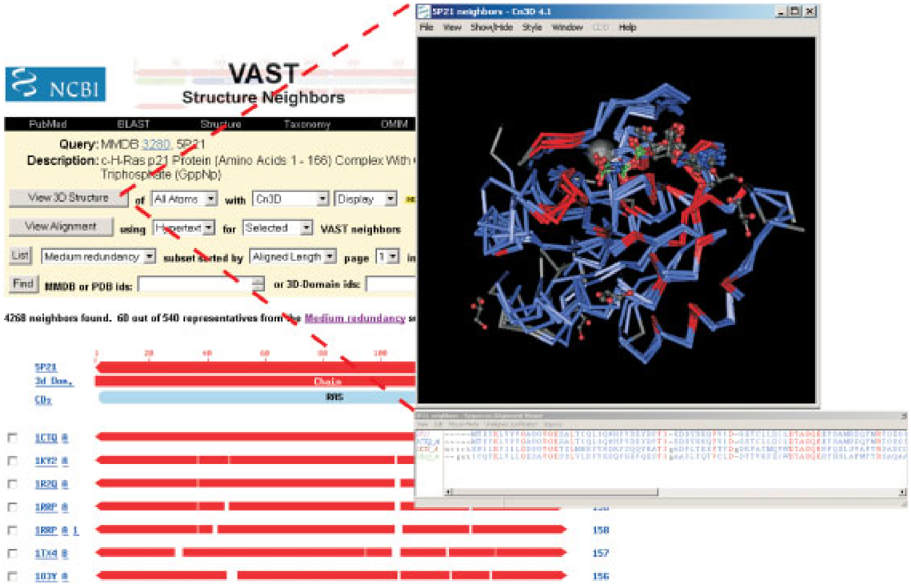

Figure 5 Structural neighbors of the human c-H-ras p21 protein (PDB/MMDB code 5p21). The user can select a subset of neighbors, click on the View 3D Alignment button launching the Cn3D application. The sequence alignment will be shown in a separate window

nonredundant list of structures. VAST Search output is a list of structure neighbors in the VAST format; the user can interactively select one or more structural matches and view the superpositions with Cn3D.

Specialist Review

Bioconductor: software and development strategies for statistical genomics

Robert Gentleman
Dana-Farber Cancer Institute, Boston, MA, USA

Vincent Carey
Brigham and Women's Hospital, Boston, MA, USA

1. Introduction

Recent technological breakthroughs have allowed biologists to investigate the fundamental mechanisms of cellular activity at an extremely fine level of detail. Numerous high-throughput technologies are available for measuring mRNA abundance, DNA copy number, and protein–protein interactions, to name but a few. Additionally, our understanding of the fundamental processes and relationships that underlie these data is growing rapidly. Appropriate analysis of the experimental data relies heavily on the ability to relate it to the existing corpus of biological knowledge as well as on sophisticated statistical analyses and machine learning techniques.

Developing software solutions that are capable of addressing even a small selection of the existent problems is a daunting task. Among the technological challenges are dealing with data size and complexity, fitting appropriate models to the data, reliably ascertaining features that differ between phenotypes, and accurately assessing predictive capabilities of the data and model. The Bioconductor project was devised to provide software solutions for specific data analytic problems and infrastructure to support the development of software solutions by other groups and individuals. The complex and dynamic nature of the problem domain suggests that viable approaches will be based on a large number of interoperable software modules or components. Among the many specific challenges that we have faced are ensuring interoperability, designing and delivering software, and providing substantial and accurate documentation. In this article, we describe and discuss some of the relevant design criteria and our experiences in the first few years of this project.

Our view is very similar to that proposed by Stein (2002), who emphasized web services as the basic computational resource for bioinformatics. We place greater emphasis on the creation and distribution of open source software modules that can

be used independently of the web. With R as a foundation for bioinformatic software development, the Bioconductor project allows, but does not require, developers to deal with issues of web-service design and deployment. R can be embedded in server side software so that services can use R's numerical, statistical, and graphics capabilities, including packages developed in Bioconductor, as needed. Given its excellent XML, SOAP, and general connection-handling facilities, interactive R can function as a richly endowed client to general external web services. An important point is that our modules are open source and hence can be extended by anyone. The same would be true for an open source bioinformatic web service.

There are many competing requirements for any software development project in this area. Substantive requirements include reduction of barriers to entry for cross-disciplinary research. Technical requirements include encouraging extensibility, modularity, transparency, and interoperability. These requirements can conflict, and a successful project must carefully maneuver amongst them.

Perl, Python, and R have all found widespread use by different bioinformatic practitioners. See articles Article 103, **Using the Python programming language for bioinformatics**, Volume 8 and Article 112, **A brief Perl tutorial for bioinformatics**, Volume 8 for background on bioinformatics scripting languages. We chose to use R, partly due to our long history with the S language (Becker *et al*., 1988; Ihaka and Gentleman, 1996) and also because we believe that it has a number of compelling advantages over both Perl and Python. In particular, R has a rich set of statistical algorithms and machine learning algorithms that are well tested. R provides very high level visualization capabilities that are easily extended to provide new tools.

2. Some details

R is an interactive interpreted language generally used from a command-line interface. It is oriented toward statistical and mathematical programming. R has pass-by-value semantics, is vector oriented, has an object-oriented paradigm (inherited from the Lisp family of languages), and the functions are first-class objects. R has lexical scope (Gentleman and Ihaka, 2000) that supports notions of encapsulation.

Like Perl and Python, R is capable of calling routines written in other languages, supports direct database connections, and has support for connections made over `http` and other protocols. Pseudorandom number generation is also important in many aspects of genomic data analysis, and R has a number of well-tested and well-implemented routines that can be used. Concurrent computation, in which one R session or program governs processing on multiple heterogeneous computers, is supported under various parallel computing protocols (e.g., packages such as *snow*, *rpvm*, *rsprng*).

Data structures in R are self-describing and these data structures are used both to store and manipulate the data that is being analyzed as well as the language itself. Because data structures are self-describing, there is no need for type declarations.

R is vector oriented and many computations are *vectorized*, which means that certain operations apply to all elements of a vector or array. Arrays and matrices are simply vectors with appropriate dimension *attributes* set.

```
> x = 1:10
> x

 [1]  1  2  3  4  5  6  7  8  9 10

> x + 1

 [1]  2  3  4  5  6  7  8  9 10 11

> dim(x) = c(2, 5)
> x + 2

     [,1] [,2] [,3] [,4] [,5]
[1,]    3    5    7    9   11
[2,]    4    6    8   10   12
```

Amongst the more powerful of the R language constructs are the subsetting capabilities. Subscripting a vector or matrix is indicated by the use of square brackets (`[]`). Many different types of subscripts are used, positive, negative, and logical subscripts are all allowed. Readers are referred to one of the many texts on the language such as Maindonald and Braun (2004) or Becker *et al*. (1988) for more details.

Nonhomogeneous data are typically stored in the *list* data structure. In many statistical applications, data are of the form samples by variables where the types of the different variables may be different; some may be numerical, others dates or character. The *data.frame* is a data type that was created to accommodate this commonly observed data format. It is essentially implemented as a list of vectors (one for each variable). List subsetting has two forms. The single square bracket operator, `[]`, returns a list of the selected elements. The double square bracket operator, `[[]]`, extracts an element of a list and returns it directly.

Functions are a basic language type, and users can readily examine system functions and easily create their own. As noted above, the semantics are those of pass-by-value so one can act on the arguments to a function as if they were a copy of the supplied value. We note that our simple function below is automatically vectorized by virtue of the fact that the multiplication operation (`*`) is. There is, in essence, no difference between the user-defined function `mysq` and any system function.

```
> mysq = function(x) x * x
> mysq(10)

[1] 100
```

```
> mysq(c(1, 3, 5))
```

```
[1]  1  9 25
```

Of some interest are the set of functions that *apply* a user-supplied function to some particular data structure. These are listed in Table 1. Both `lapply` and `sapply` can be applied to lists and the main difference is that the latter will return a vector, if possible. For `apply`, any matrix or array can be used as the object to apply to, but the user must specify which dimension to collapse over.

```
> le = list(a = c(1, 3, 5), b = 2, c = mean)
> sapply(le, length)
```

```
a b c
3 1 1
```

```
> me = matrix(1:9, nc = 3)
> apply(me, 1, mean)
```

```
[1] 4 5 6
```

3. The anatomy of an R package

The primary method of delivering software tools in R is as packages. A *package* is a collection of software, data, manual pages, and other documentation and resources that have been created and combined, typically to address a particular statistical problem.

R provides substantial infrastructure resources for package creation, maintenance, and unit-testing procedures. Users can create distributable software modules that include documentation, on a variety of levels, and which can be extended by others. The unit-testing features are well developed and greatly aid in quality control. Given our belief that appropriate solutions will be developed in a wide community, any language, or system, that supports that development will need to have substantial package creation and distribution tools.

Table 1 The apply functions

Name	Type of argument
apply	matrix
tapply	ragged array
lapply	list
sapply	list

An R package is a set of files and folders, some of which have specific names. Many more details are given in the R Extension Manual (R Development Core Team, 1999), which is the definitive reference for packages and many aspects of R. We list the most important set of these below:

- `DESCRIPTION`: A file in the main folder that provides various declarative statements about the package. These include its name, the version number, the maintainer, and any dependencies on other packages (as well as several other things).
- `R`: A folder that contains all of the R code for the package.
- `man`: A folder that contains the manual pages for the functions in the package.
- `src`: A folder that contains the source code for any foreign languages (such as C or FORTRAN) that will be used.

The development cycle begins by creating the structure of a package, often using the R function `package.skeleton`. The specific details are then filled in, code added and tested, and manual pages written. Manual pages are stored in a special R language markup that is also described in the R Extension Manual and their creation is often facilitated by the use of the function `prompt`. Among the most important aspects is that the developer provide appropriate examples, demonstrating proper usage of code, on per function basis.

Once the developer is comfortable that their package is ready for distribution, they should engage in unit testing and checking. The R system has a sophisticated, although sometimes cryptic, software verification system. Issues such as consistency between the code (in the `R` folder) and the documentation (in the `man` folder) are evaluated. At the same time, all examples that have been provided are run. Any errors or inconsistencies are reported and the developer should fix the defects and again run the checking system.

Packages that have passed the checking process are ready for others to use. The developer can choose to distribute it or they can upload it to either the CRAN (**www.cran.r-project.org**) or the Bioconductor packages repository (**www.bioconductor.org**), where users can easily obtain a copy. Packages are typically distributed in the form of compressed OS-specific archives.

There are a number of tools provided with R that allow users to automati cally download and install R packages from any of the standard repositories. When a developer updates their package, the version number should increase. That change will alert users to the existence of a new version and will greatly facilitate tracking down errors and inconsistencies. In addition, functionality provided by `update.packages` allows users to detect out-of-date packages and to update all R packages on their computer to a current and mutually compatible set.

Computations programmed in one Bioconductor package routinely depend upon code provided in other packages. As packages evolve independently, it transpires that particular sets of versions of packages may be required for successful interoperation. Version management is a complex task for both developers and users, and software can reduce the complexity and risk of error in creating or maintaining a consistent set of versions. We have developed a new set of routines that simplify a number of aspects of package management. The package *reposTools* includes a definition of an external repository, which includes a table indexing package

Table 2 Some R and Bioconductor packages

Preprocessing	Differential expression	Visualization	Machine learning
affy	limma	geneplotter	class
marray	genefilter	hexbin	cluster
vsn	multtest	Rgraphviz	e1071
PROcess	siggenes	rgl	randomForest

versions and interdependencies, functions that harvest the repository for software addressing certain tasks, functions that collect sets of packages that have mutually consistent versions for interoperation, and tools that allow developers to define and manage their own public repositories.

In Table 2, we list a small number of the very many available R packages that will be of interest to researchers and data analysts working on computational biology and bioinformatics problems. We provide only a small sample of the several hundred packages that are now available. This is not an endorsement of any, but rather a sample selected to have potential interest to many readers. Readers should consult either CRAN or Bioconductor web pages for complete descriptions of the packages and their contents.

4. Documentation

One cannot overemphasize the importance of documentation. Well-written and comprehensive documentation allows the users to make full use of the supplied software. However, early in the Bioconductor project we identified a problem with the usual software documentation paradigm. It is centered on describing the inputs and outputs of specific functions. And while this is essential for using the functions, it does not provide the users with any view of how the different functions can be *used* to carry out a particular analysis.

We developed the vignette concept to deal with the problem of describing complete tasks or analyses. Vignettes use the Sweave system (Leisch, 2002) to provide documents that integrate code and text in a seamless fashion. These documents can be transformed to provide different outputs. In one transformation, the code is evaluated in R and it is replaced by the output, and from this a PDF document is created and users may read this. A second transformation is to extract all of the code chunks into a separate file. Users can examine this file to see what R code was used to create each of the figures, tables, and other outputs reported. To guide users through the sequential evaluation of code chunks, we developed a widget called `vExplorer` in the *tkWidgets* package. Users can open any vignette in the explorer and they are presented with each code chunk in turn; they can examine it, replace some of the code if they desire, and then evaluate it.

All vignettes provided with a package are also checked during the package-checking phase. These vignettes provide a different aspect of quality control. They help to ensure that inputs and outputs of the different functions being employed are kept synchronous and can be used to test more complex interactions.

5. Meta-data packages

Microarray experiments provide information on a specific subset of genes (those with probes on the microarrays that were used). In order to facilitate the use of biological meta-data such as chromosomal location, gene name, gene symbol, Gene Ontology annotations, pathway involvement, and so on, we developed the meta-data package. These are valid R packages that contain the meta-data for a specific microarray chip. The data items are stored in hash tables (called *environments* in R), with the primary key being the manufacturers identifier, in most cases.

Users need only identify the chip that they are using to locate and download the appropriate meta-data packages. The chip-based meta-data packages are auto-generated using tools in *AnnBuilder* (Zhang *et al*., 2003) and are homogeneous with respect to the data that are contained in them. If a user moves from one chip to another (even from oligo-arrays to spotted arrays), the data format remains constant.

6. Design and development issues

6.1. Software reuse

In many cases, one can locate software tools that provide the necessary functionality but which have not been written in R (or whichever language is being used for development). While one can always reimplement the software, this is inefficient and error prone. Wherever possible, software reuse should be the guiding principle. One of the tools that makes this possible is the ability to access code written in other languages (or what might be termed *a foreign function interface*). This interface is very systematized in R, and is documented in the R Extensions manual. Similar functionality is found in most high-level languages.

In creating software for graphs and networks, we relied on two other projects. The BOOST Project (**www.boost.org**) that provides a C++ implementation of many different graph algorithms and Graphviz (**www.graphviz.org**) that provides a C implementation of several different graph layout algorithms. The two R packages, *RBGL* and *Rgraphviz*, provide interfaces to these two substantial pieces of software. We could not have reimplemented these in the time frame available, nor if we had tried would we have been likely to write software that was of the same quality.

By creating interfaces between R and the C and C++ code from these two projects, we have been able to provide the necessary functionality to users, within R, with relatively little effort on our part. Further, with regard to Graphviz, the interactions have sparked some interesting collaborations, as telecommunications scientists have become interested in the specialized layout problems that exist in biological applications.

6.2. Encouraging interoperability

One of the most difficult tasks in distributed software development is promoting and maintaining interoperability. Interoperability is fostered when specific data

structures and software obligations are made explicit and public. Such explicit and public specifications allow different individuals to contribute modules specific to their domains, which can then be reused (or modestly transformed according to precise specifications) for analyses relevant to other domains.

A shared data model is one of the essential ingredients of interoperability. If all modules are written in the same language, then a *class* definition can be made to describe the structure of each data object that is of interest. When different languages are involved, the requirement is that each language be able to query the other languages to determine their view of the data objects. This is generally termed *reflectance* and is most commonly provided by the language's class definitions. However, there are alternatives such as standardized XML markups that are shared.

6.3. Speed and efficiency

In any software project, speed and efficiency can have a myriad of meanings. Scripting languages (*see* Article 103, **Using the Python programming language for bioinformatics**, Volume 8 and Article 112, **A brief Perl tutorial for bioinformatics**, Volume 8) and R have the property that it is relatively easy to create a working version of an idea very quickly. The running time of that early version might not be especially fast, but the development itself can be exceedingly rapid. In a field like bioinformatics and computational biology where the correct way, or even a good way, to carry out specific tasks is generally not known, we believe that this form of efficiency, that is, *efficiency of development*, should take priority.

Once the idea has been proven to work and to be of substantive value, efforts can be made to speed up the software. At this point, we can draw on some of the software engineering code provided by R and carry out substantial profiling experiments. These typically identify specific bottlenecks that can be alleviated either by an altered design or by making use of the foreign function interface and simply calling a compiled language such as C.

7. Examples

We now provide two examples where R/Bioconductor is used to solve some practical and relevant bioinformatic problems.

7.1. Querying the literature

Biological meta-data is constantly evolving. New initiatives are constantly emerging for improved categorization and distribution of data on genomes, SNPs, transcription factors, and so forth. In the subsection on meta-data packages above, we described one method for dealing with meta-data, organizing snapshots of them into the equivalent of local databases. For many of the popular microarrays, these have been precomputed and are available through the Bioconductor project. A different, and complementary, strategy is to provide on-line access to any available data source that provides a web-services interface.

Different initiatives through the NCBI provide well-defined interfaces to a variety of data sources. As part of the *annotate* package, we have developed a set of tools that allow users to access these data, in real time, from within the R session. There are several options, and the interested reader is referred to the documentation in that package for more explicit details. Here we provide code to demonstrate some of the simpler operations that one might want to carry out.

In the code below, we presume that the LocusLink identifiers for the genes we are interested in are contained in the variable named `ids`. We generate the query and store the results in a variable named `x`. This object is of class `XMLDocument` and to manipulate it we will use functions provided by the XML package.

```
> x <- pubmed(ids)
```

```
Loading required package: XML
```

```
> a <- xmlRoot(x)
> numAbst <- length(xmlChildren(a))
> numAbst
```

```
[1] 59
```

Our search of the 59 PubMed IDs (from the 11 Affymetrix IDs) has resulted in 59 abstracts from PubMed (stored in R using XML format). The *annotate* package also provides a `pubMedAbst` class, which will take the raw XML format from a call to `pubmed` and extract the interesting sections for easy review.

```
> arts <- vector("list", length = numAbst)
> absts <- rep(NA, numAbst)
> for (i in 1:numAbst) {
+ arts[[i]] <- buildPubMedAbst(a[[i]])
+ absts[i] <- abstText(arts[[i]])
+ }
> arts[[7]]
```

```
An object of class pubMedAbs
Slot "pmid":

tat....

Slot "journal":
[1] "Nature"

Slot "pubDate":
[1] "Jan 1994"

Slot "abstUrl":
[1] "No URL Provided"
```

Once the abstracts have been assembled, they can be searched by standard search techniques. Suppose, for example, we wanted to know which abstracts include the term `cDNA`. The following code chunk shows how to identify these abstracts.

```
> found <- grep("cDNA", absts)
> goodAbsts <- arts[found]
> length(goodAbsts)

[1] 19
```

So, 19 of the articles relating to our genes of interest mention the term `cDNA` in their abstracts.

Many users find it useful to have a web page created with links for all of their abstracts, leading to the actual PubMed page on-line. These pages can then be distributed to other people who have an interest in the abstracts that you have found. See Figure 1 for an example of the software-generated hypertext abstract listing achievable with the pmAbst2HTML function of the annotate package.

7.2. Networks

New challenges to be faced include the statistical analysis of network/pathway data as well as meta-analyses of several different data sources, possibly derived from different technologies. Through the implementation of packages to handle graphs and graph algorithms within R, we have at our fingertips the tools needed to begin more complex modeling processes.

We will illustrate how simply new tools can be implemented and distributed using the software infrastructure we have developed. We consider the method of Zhou *et al*. (2002) for discovering "transitively coexpressed" genes. This methodology, implemented using data from yeast microarrays, defines a concept of coexpression based on shortest paths in a graph. The nodes of the graph are given by genes and edge lengths are defined by a transformation of correlation in expression values over a collection of diverse experiments. Declarations of coexpression are made when functional relationships between genes on shortest paths are established using Gene Ontology.

Zhou *et al*. (2002) present the procedure in two phases: a validation phase confines attention to genes with known annotation and measures the extent to which transitive coexpression agrees with functional annotation; an application phase uses

transitive coexpression to predict functions of relatively unstudied genes. In this summary, we focus on the validation phase, which includes a number of tuning parameters. The basic data objects of the analysis are

- $M = [m_{ij}]$, a matrix of expression experiment results with i indexing genes and j indexing experiments,
- $C(a, b)$, a function that computes a robust correlation coefficient between two vectors a and b as the minimum in absolute value of the Pearson correlations,
- K_c, the complete graphs on all yeast genes in cellular component $C \in$ {mitochondria, cytoplasm, nucleus}, with edge between genes g_p and g_q initially assigned length $C(m_{p\cdot}, m_{q\cdot})$,
- the GO DAGs for biological process and cellular component.

We will focus attention on a single cellular component and thus drop the subscript for K; the same process is used for each component. The algorithm is:

1. Form K' by removing edges in K with length less than $\tau = 0.6$.
2. Recompute K' edge length $w_{new} = [1 - w_{old}]^k$, where $k = 6$.

3. Stratify GO annotations into informative and uninformative, with an informative term satisfying the conditions that (a) it is used for annotation at least $\gamma = 30$ times and (b) all immediate refinements of the term are used less than γ times.
4. Enumerate all shortest paths between all pairs of genes (denoted *termini*) annotated to informative GO terms.
5. Discard paths of length greater than $\sigma = 0.008$.
6. Characterize genes along the path between the termini as L0 matches if they are annotated to the same term as the termini, or as L1 matches if they are annotated to a term that shares the same immediate ancestor with the term to which the termini are annotated.
7. Compute permutation-based null distributions of "match ratios" (ratio of number of L0 or L1 matches to total number of transitive genes) for significance appraisal.

This procedure can be implemented fairly directly using basic resources in Bioconductor (see the *GOstats* package). The expression matrix M is best represented as an *exprSet*. The robust correlation function can be straightforwardly coded in R or C; note that `cov.rob` implements high-breakdown correlation estimation, which may be more effective than the leave-one-out procedure adopted by the authors. Given a distance structure (readily computable by any correlation function), the *graph* package *distGraph* class computes K and the `threshold` method computes K' from K. Edge weight transformation is performed by `apply`. Shortest-path computations are carried out through the interface to the Boost graph library, using either `dijkstra.sp` or `sp.between`; the enumeration of pairs of termini is efficiently computed by the *combinat* package. Operations on the GO graph and its association to yeast genes can be carried out directly using package *graph*, or by using an object-ontology complex as defined in *ontoTools*. *ontoTools* supports computation of semantic similarity of ontology terms, facilitating more fine-grained measurement of degree of "functional match" among transitive genes than the L0/L1 dichotomy. Computational inference via node relabeling is straightforwardly carried out using aspects of the *graph* representation of the *graph* package.

A key point to keep in mind when considering the Bioconductor approach to bioinformatic data analysis is the commitment to transparency and extensibility of the analytic tool. We have described separately implemented structures or modules that are plugged together to perform the analysis for a generically characterized input matrix M. Distance computations and thresholding procedures should be kept separate and all tuning parameters should be exposed to facilitate sensitivity analysis. The only special-purpose programming required is the "glue", the top-level function that accepts user parameters and coordinates the application of the different components. The glue serves as a precise specification of the high-level computation, and the individual components are separately documented and verified according to Bioconductor principles.

Through the application of well-designed modular software, this interesting idea can be turned into a functional program in an afternoon. The end result is more general than the original description and can be shared as the author desires.

8. Discussion

Our proposal, and the direction of the Bioconductor project, is for the creation of highly interoperable software modules that are easy to obtain, platform neutral, and self-documenting. A web-services model provides a different abstraction of essentially the same idea. Web services are conceptually quite similar to software packages or modules, and virtually the same set of problems needs to be addressed by either approach. When web services are open source, then they can be extended and modified to suit local purposes. But, in some ways, they are more complex than packages. Web services are language-neutral black boxes for the users but they are not for developers; each one typically has its own idiosyncrasies. By choosing to use a common language and an open source development model, we hope to make it easier for others to adopt, adapt, and extend our work.

Data analysis software components that are transparent, that are sufficiently generic to warrant reuse in multiple contexts, and that allow analysts to maintain fidelity to the biological concepts of interest are at a premium in furthering objective scientific progress at this crucial juncture. While we are in some ways agnostic to the delivery mechanism (different investigators will have good reasons to use virtually every language that is at all relevant), we do believe that the S language is well suited to this domain of application.

Different developers will always have different ideas on how to solve a given problem. We are convinced, however, that modular and interoperable designs and deployments are achievable at acceptable cost by most researchers and developers in this field, regardless of the details of tools and methods chosen. The standards of transparency and explicit reproducibility that are well accepted in wet-lab science have not propagated to the in silico domain of computational biology. The Bioconductor project is an attempt to demonstrate that these standards can be met in effective and widely used analytic software for bioinformatics. Bioconductor would not be possible but for the extraordinary dedication and ingenuity of its core members and its active user community. To them we offer heartfelt thanks.

Acknowledgments

Specialist Review

RNA secondary structure prediction

David H. Mathews

University of Rochester Medical Center, Rochester, NY, USA

Michael Zuker

Rensselaer Polytechnic Institute, Troy, NY, USA

1. Introduction

RNA is increasingly being discovered to play many roles in Biology aside from its two functions in the Central Dogma. RNA is now known to have roles in peptide bond catalysis (Hansen *et al*., 2002), RNA editing and intron splicing (Doudna and Cech, 2002), protein shuttling (Walter and Blobel, 1982), immunity (Cullen, 2002; Lau *et al*., 2001), development (Lagos-Quintana *et al*., 2001), dosage compensation (Panning and Jaenisch, 1998), posttranscriptional gene regulation (Wellbacher *et al*., 2003), and RNA modification (Bachellerie *et al*., 2002). Novel catalytic RNA sequences can be evolved in vitro to extend the functionality of nucleic acid sequences (Bittker *et al*., 2002). RNA is also a target for pharmaceutical design either through antibiotics that target rRNA, antisense oligonucleotides (Dias and Stein, 2002), mis-splicing redirection (Sazani and Kole, 2003), or catalytic ribozymes (Long *et al*., 2003). Because of the relationship between structure and function, a detailed understanding of the structure of an RNA is needed for understanding the mechanism of action of that RNA.

RNA structure is commonly divided into levels of complexity. The primary structure is the sequence of nucleotides; secondary structure is the sum of canonical pairs, that is, Watson–Crick and G·U pairs; and tertiary structure is the three-dimensional arrangement of atoms. In general, the base pairs of secondary structure are significantly more stable than tertiary contacts (Brion *et al*., 1999); therefore, in practice, the secondary structure can largely be determined independently of tertiary structure.

The accepted standard for determining RNA secondary structure, in the absence of a crystal structure, is comparative sequence analysis. A recent study demonstrated that 97% of base pairs predicted on the basis of comparative sequence analysis are found in the high-resolution crystal structures of ribosomal RNA (Gutell *et al*., 2002). Accurate comparative sequence analysis, however, requires a large number of homologous sequences often obtained from multiple species or

from in vitro evolution. Even when a large number of homologous sequences is available, the alignment and deduction of secondary structure can be exceedingly difficult, as in the case of eukaryotic RNase P (Frank *et al*., 2000).

In the absence of a large number of related sequences, methods have been developed for predicting RNA secondary structures. This article reviews many of the current methods for secondary structure prediction, including methods for finding common structures in related sequences.

2. Nearest-neighbor parameters

Most secondary structure prediction algorithms use the principle of free energy minimization to predict base pairs, where the free energies of RNA secondary structures are predicted using a set of nearest-neighbor parameters based on optical melting experiments (Mathews *et al*., 2004; Mathews *et al*., 1999; Xia *et al*., 1998). Base pairs contribute favorable free energy increments. Loop regions contribute unfavorable free energy increments for initiation, largely because of the entropic penalty associated with restricting nucleotides into loop regions, and favorable increments that are sequence specific.

A recent revision to the free energy rules (Mathews *et al*., 2004) accounts for data from several recent experimental studies for bulge loops of a single nucleotide (Znosko *et al*., 2002), hairpin loops (Dale *et al*., 2000), multibranch loops (Diamond *et al*., 2001; Mathews and Turner, 2002b), and internal loops (Schroeder and Turner, 2000; Schroeder and Turner, 2001). The recent hairpin loop optical melting data generally supports the accepted model for predicting hairpin loop stability (Dale *et al*., 2000). The bulge loop study is the first systematic study of the effect of sequence for the stability of single nucleotide bulges by optical melting (Znosko *et al*., 2002). The multibranch loop studies present the first quantitative data for multibranch loop free energies in RNA, and are used as a basis for the revision of the equation used to predict multibranch loop initiation free energies (Diamond *et al*., 2001; Mathews and Turner, 2002b). Finally, the internal loop studies demonstrate idiosyncrasies in the sequence dependence for internal loop stability (Schroeder *et al*., 1999; Schroeder and Turner, 2000; Schroeder and Turner, 2001). For example, the G·G mismatch has a favorable free energy increment in 2×3 internal loops, but is worth no extra stability in $1 \times n$ internal loops, where n is greater than 2.

3. Free energy minimization by dynamic programming

Given that the free energy for an RNA secondary structure can be estimated for any sequence, several algorithms have been devised to predict a secondary structure from sequence. The naïve approach would be to explicitly generate all possible secondary structures for the sequence, evaluate their free energies, and then find the lowest energy structure. But, the number of possible structures increases exponentially with the length of the sequence, making this approach infeasible. Dynamic

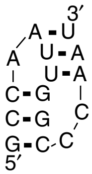

Figure 1 A simple pseudoknot. This secondary structure illustrates the simplest pseudoknot, formed when the nucleotides in a hairpin loop pair to nucleotides either 3′ or 5′ to the hairpin loop stem

programming algorithms were the first practical algorithms used to solve this problem (Nussinov and Jacobson, 1980; Zuker, 1989; Zuker and Stiegler, 1981).

The important feature of dynamic programming is that recursion is used to determine folding free energies. For the most popular algorithms, the recursions result in a calculation that is O(N^3), where N is the number of nucleotides (Hofacker *et al*., 1994; Mathews *et al*., 2004). This means that a doubling in the length of the sequence results in an eightfold increase in calculation time. Intermediate energies are calculated for structures restricted to subsequences of the entire sequence, resulting in O(N^2) storage. To maintain this scaling, these algorithms are unable to predict structures containing pseudoknots, illustrated in Figure 1. The currently available dynamic programming algorithms for RNA secondary structure prediction also limit the size of internal loops. Lyngsø *et al*. (1999) developed a method for predicting internal loops in O(N^3) time without having to limit the size of internal loops.

Modern implementations of energy minimization dynamic programming algorithms predict not only the lowest free energy structure but also an ensemble of structures with free energy close to the minimum, called *suboptimal structures* (Mathews *et al*., 2004; Zuker, 1989; Zuker, 2003). These structures, sampled heuristically, demonstrate other base pairs that are alternatives to the pairs in the lowest energy structure. In addition, the information contained in suboptimal structures can be summarized with a two-dimensional energy dot plot that shows, for each possible i–j pair, the lowest free energy possible for a structure containing that pair (Jaeger *et al*., 1989; Zuker, 1989). Suboptimal structures are important because some RNA sequences populate more than one structure in solution (Schultes and Bartel, 2000) and because of the errors inherent in the nearest-neighbor parameters.

Currently, predicted RNA secondary structures contain, on average, 73% of known base pairs for RNA sequences divided into domains of less than 700 nucleotides (Mathews *et al*., 2004). On average, the best of 750 suboptimal secondary structures contains 86% of known base pairs. This accuracy can be improved by using data derived from experiments (Mathews *et al*., 2004; Mathews *et al*., 1999) using single-stranded or double-stranded specific enzymes, flavin mononucleotide cleavage that can reveal Us in G·U base pairs (Burgstaller *et al*., 1997), or chemical modification data from either in vivo or in vitro probing.

Dynamic programming algorithms for RNA secondary structure prediction by free energy minimization are available from three sources. Mfold is a program for on-line folding or compilation on Unix or Linux (Zuker *et al*., 1999) and can be accessed at **http://www.bioinfo.rpi.edu/applications/mfold** (Zuker, 2003).

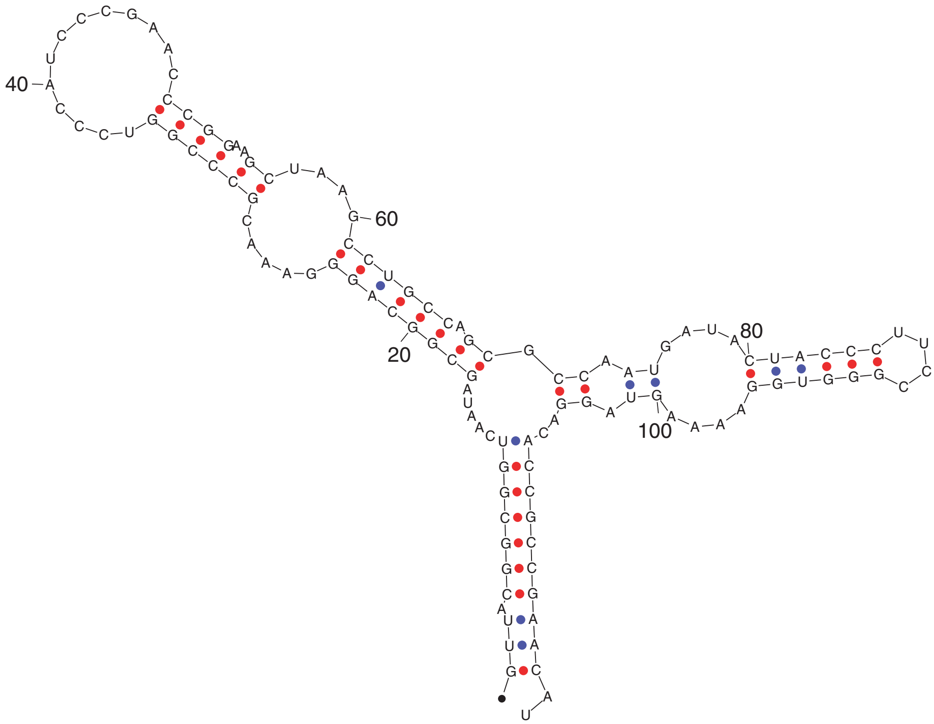

Figure 2 Secondary structure prediction of *M. phlei* 5S rRNA. This is sample output for secondary structure prediction by the mfold Web Server. The sequence was taken from the 5S rRNA database (Szymanski *et al*., 2000)

Figure 2 illustrates the secondary structure prediction output from the Mfold server. The Vienna RNA Package includes RNAfold for RNA secondary structure prediction. It is available as an on-line server, as a code for local compilation, or as Microsoft Windows binaries at **http://www.tbi.univie.ac.at/~ivo/RNA/** (Hofacker, 2003). RNAstructure is a program for the Microsoft Windows environment that uses a graphical user interface and includes RNA secondary structure prediction (Mathews *et al*., 1999). It is available for download from the Turner lab website, **http://rna.urmc.rochester.edu/RNAstructure.html**. The three RNA folding packages differ slightly in their implementation of the nearest-neighbor energies in multibranch loops and exterior loops; therefore, different structures can sometimes be predicted by each program.

Variations on the standard dynamic programming algorithm for free energy minimization are available for specialized calculations. The Vienna RNA Package includes a program, RNAsubopt, for generating all suboptimal secondary structures for a sequence within a user-defined energy increment from the lowest free energy (Wuchty *et al*., 1999). Although the number of suboptimal structures increases exponentially with increasing size of the energy increment, this algorithm can reasonably sample, for example, all 295 722 suboptimal structures within 12 kcal mol^{-1} of the minimum free energy conformation for a sequence of 75 nucleotides (Wuchty *et al*., 1999).

An interesting dynamic programming algorithm was introduced by Rivas and Eddy (1999) demonstrating that a broad class of structures containing pseudoknots can be predicted by dynamic programming in polynomial time. Their algorithm, called PKNOTS, can predict a subset of pseudoknotted structures that sufficiently covers all topologies of practical interest, although the general problem of finding any possible pseudoknot has been shown to be NP-complete (Lyngsø and Pederson, 2000). The drawback is that the algorithm is O(N^6) in time and O(N^4) in storage, making it intractable for sequences much longer than a few hundred nucleotides. The code is available for download at **http://www.genetics.wustl.edu/eddy/software/**.

4. Other secondary structure prediction algorithms

The problem of finding the lowest free energy structure for an RNA sequence has also been approached by the use of a genetic algorithm. Secondary structures are randomly mutated, and those mutations that are most “fit”, on the basis of free energy, are kept for future rounds of mutation. “Unfit” mutations are discarded. At some steps, solutions are crossed from multiple structures to find new structures and are evaluated on the basis of free energy. The advantage of one such program, called STAR (Gultyaev *et al*., 1995), is that folding pathways can be modeled using a sequence that lengthens from the 5′ end in the same way a sequence elongates from the 5′ end during transcription. Predicted helices with low free energy are less likely to rearrange as the sequence elongates. Computational experiments show that STAR is more accurate when a sequence is folded as it is elongated from 5′ to 3′ than when the entire sequence is folded at once. This suggests that kinetic traps of stable structure are important for at least some RNA sequences. STAR is available at **http://wwwbio.leidenuniv.nl/∼Batenburg/STROrder.html**. The drawback of these calculations is that multiple calculations on the same sequence can converge to different structures with different energies.

A two-dimensional polymer theory model that can construct an energy landscape for RNA folding was developed (Chen and Dill, 2000). This method uses the helical nearest-neighbor parameters (Xia *et al*., 1998), but extrapolates energies for loop regions from chain entropies. The resulting landscapes suggest that RNA folding may be fundamentally different than protein folding because the RNA landscape may be more rugged.

Stochastic context-free grammars have also been adapted to the prediction of RNA secondary structure.

5. Partition function calculation

McCaskill (1990) presented a novel dynamic programming algorithm that calculates the partition function for RNA secondary structure and that can predict the probability of base pairing for all possible base pairs. This algorithm is O(N^3) in time and O(N^2) in storage. It has been implemented with recent sets of thermodynamic parameters in the Vienna RNA package (Hofacker, 2003; Hofacker *et al*., 1994)

and in RNAstructure (Mathews, 2004). Figure 3 illustrates a probability dot plot, used for displaying all base pair probabilities, as predicted by the Vienna Web Server.

Recently, the partition function method was extended to explicitly include pseudoknots using the dynamic programming (Dirks and Pierce, 2003). Rivas and Eddy (1999) determine the minimum free energy for any secondary structure on subsequence from nucleotides *i* to *j* (including pseudoknots) as the minimum over several cases. These cases are exhaustive, but not exclusive, that is, there are secondary structures S that are considered by more than a single case. When extending

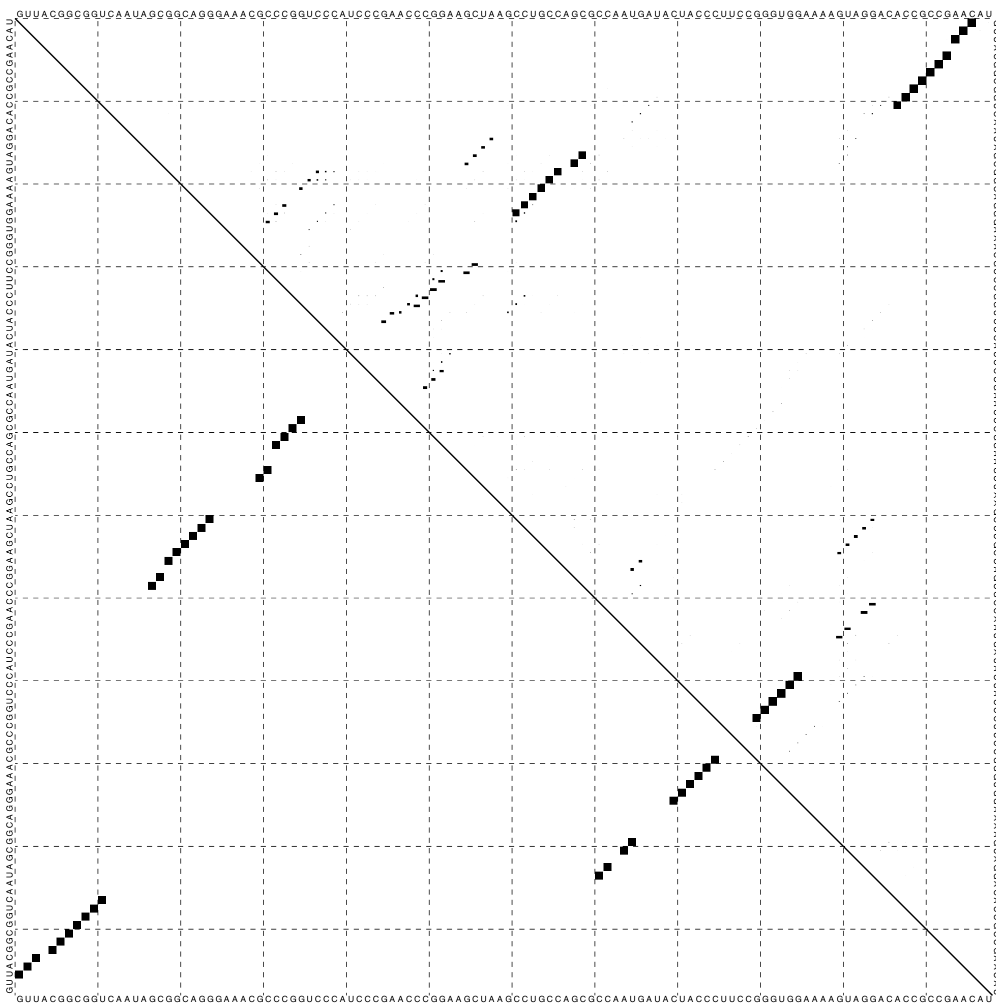

Figure 3 Probability dot plot for *M. phlei* 5 S rRNA as predicted by the Vienna Package Web Server. The lower triangle contains dots representing base pairs in the predicted lowest free energy structure. The upper triangle illustrates the probability of the ensemble of possible canonical base pairs with the area of the dot in proportion to the base pairing probability

energy minimization to the computation of the partition function, it is necessary to first devise recursions where cases are exhaustive and exclusive (or nonredundant). Dirks and Pierce (2003) do this and subsequently extend the algorithm to a computation of the partition function. This algorithm nicely incorporates the work of Lyngsø *et al*. (1999) to predict internal loops of any size using $O(N^3)$ steps.

The partition function predicts base pair probabilities, but does not, in itself, provide a method for the prediction of secondary structures. Ding and Lawrence (2003) have developed an elegant method for sampling secondary structures from the partition function to derive a statistically valid ensemble of structures. They have demonstrated, using a statistically valid sample of structures, that features dependent on secondary structures, such as binding accessibility, can be calculated that correlate with experimental measures (Ding and Lawrence, 2001).

6. Predicting a secondary structure common to two sequences

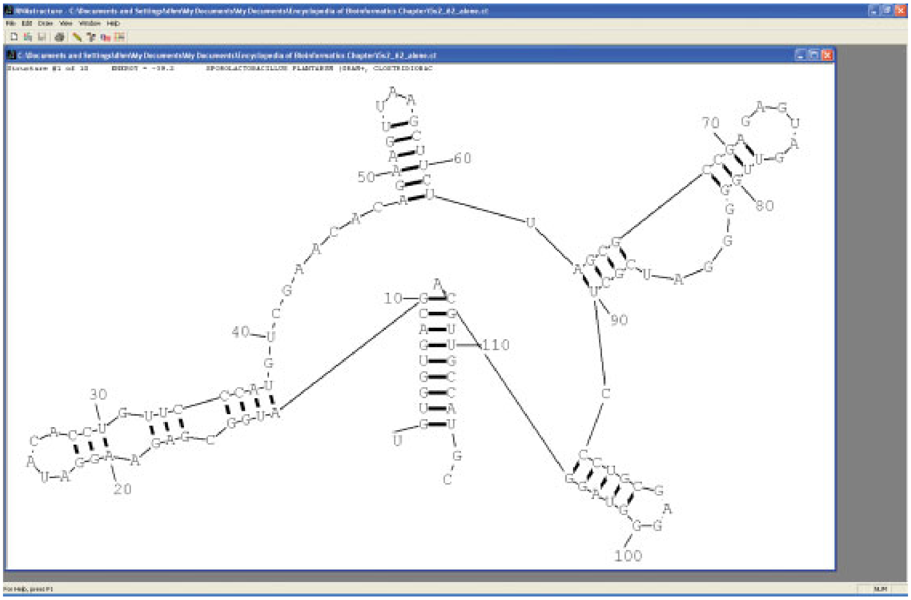
When two or more homologous RNA sequences are available, it is assumed that both sequences will adopt the same (or very similar) secondary structure. Many algorithms have become available in the last 10 years to take advantage of the auxiliary data provided by more than a single sequence. In general, these algorithms are divided into those that use a fixed alignment and those that do not require a fixed alignment. The algorithms that do not assume a fixed alignment are more robust, but take significantly more calculation time.

6.1. *Methods assuming a fixed alignment*

Two distinct approaches exist for finding a structure common to a fixed multiple sequence alignment. The first approach is to predict the structures for each sequence individually and then postprocess these data based on a sequence alignment (Lück *et al*., 1999). The ConStruct algorithm, by Lück *et al*. (1999) calculates the base pairing probabilities for each sequence using the partition function algorithm from the Vienna Package (Hofacker *et al*., 1994). The base pairing probabilities are assembled into a single consensus probability matrix according to a multiple sequence alignment and then a graphical user interface allows the user to adjust the alignment manually to optimize the base pairing probabilities. This algorithm is $O(SN^3)$, where S is the number of sequences and N is roughly the average sequence length. The source code for ConStruct is available at **http://www.biophys.uni-duesseldorf.de/local/ConStruct.html**.

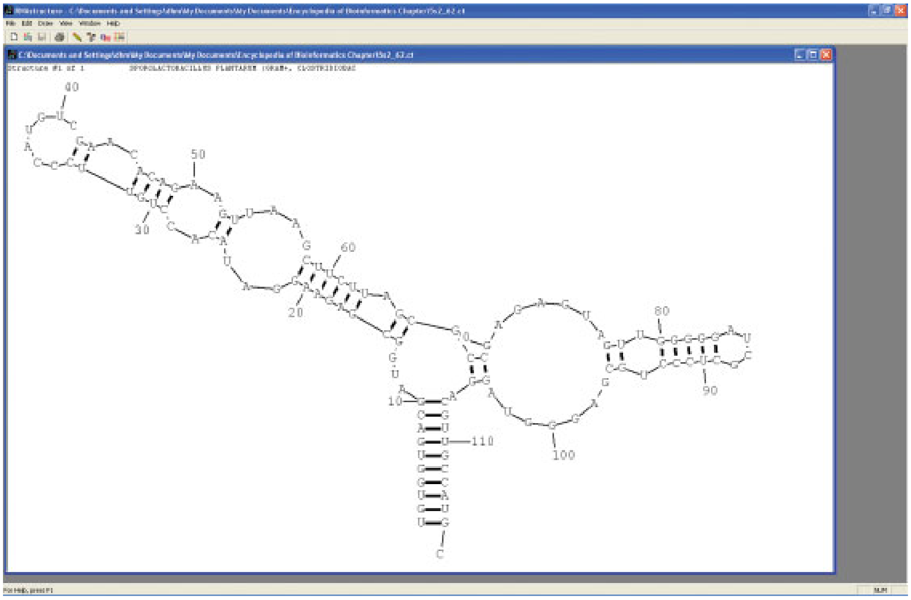
The second approach to finding a common structure in aligned RNA sequences is to use the sequence alignment to constrain a single secondary structure prediction for multiple sequences (Hofacker *et al*., 2002). The Vienna RNA package includes a program called RNAalifold that uses the free energy nearest-neighbor parameters to predict the base pairing probabilities and the minimum free energy structure for a consensus sequence derived from a multiple alignment. This algorithm is $O(N^3)$ in time where N is the total length of the sequence alignment, including nucleotides and gaps.

A specialized stochastic context-free grammar has been developed to predict a "most probable" alignment together with a common fold for a group of homologous RNAs with reasonably similar sequences (Knudsen and Hein, 1999). It has been implemented in a software package named PFOLD.



6.2. *Methods that simultaneously predict secondary structure and alignment*

Two distinct computational approaches exist to simultaneously find the common structure and sequence alignment of more than one sequence. The first proposed solution is a dynamic programming algorithm (Sankoff, 1985), but this method is in general $O(N_1^3 \times N_2^3 \times N_3^3 \ldots)$ where N_x refers to the length of sequence x. Therefore, practical solutions are currently limited to two sequences at most.



FOLDALIGN is a dynamic programming algorithm that finds local structure and alignment in two RNA sequences by maximizing a score that favors sequence similarity, base pairs, and compensating base changes (Gorodkin *et al*., 1997). The algorithm does not allow multibranch loops in order to limit the scaling in time to $O(N_1^2 N_2^2)$. Multiple pairwise predictions can be assembled into a multiple alignment using a greedy algorithm, a heuristic method common in computer science. An on-line server and the source code for FOLDALIGN are available at **http://www.bioinf.au.dk/FOLDALIGN/**.

A second dynamic programming algorithm, Dynalign, finds the lowest free energy structure common to two sequences and the sequence alignment, using a complete set of nearest-neighbor parameters (Mathews and Turner, 2002a). It allows multibranch loops, but remains $O(N^3 M^3)$ with $M \ll N$, where M restricts the set of possible alignments and N is the shorter of the two sequences. For example, for nucleotide a_i from sequence one to align with b_j in sequence two, $|i - j| \leq M$. The algorithm was tested using tRNA and 5 S rRNA sequences that are, on average, poorly predicted using a single sequence. For 156 pairwise structure predictions of 13 tRNA sequences, Dynalign predicted, on average, 86.1% of known base pairs as compared to an average of 59.7% accuracy for free energy minimization of a single sequence. Similarly, for seven 5 S rRNA sequences, the accuracy of structure prediction improved from 47.8 to 86.4% by using pairwise structure prediction with Dynalign. Dynalign is available as part of the RNAstructure package for Microsoft Windows or for local compilation by download at **http://rna.urmc.rochester.edu**. Figure 4 demonstrates the utility of Dynalign with an example drawn from 5 S rRNA.

A second solution to the problem of simultaneous folding and alignment is a genetic algorithm (Chen *et al*., 2000). This algorithm is capable of handling multiple sequences, and is $O(n^2 m^2 S^2)$, where n is the maximum number of stems for each structure, m is the maximum number of structures considered for each sequence, and S is the number of sequences. On average, 87.7% of known base pairs were correctly predicted for a set of 20 tRNA sequences and 95.3% of known base pairs were correctly predicted for 25 5 S rRNA sequences. This compares favorably to an average accuracy of 83.0% and 77.7% for tRNA and 5 S rRNA, respectively, for free energy minimization of single sequences. The

(a)

(b)

Figure 4 Dynalign improves the accuracy of secondary structure prediction by using mutual information in two sequences. (a) shows the secondary structure predicted for the *S. plantarum* 5 S rRNA sequence by standard free energy minimization. Note that this structure is poorly predicted. For example, it has five branches from the central multibranch loop instead of the known 3-way multibranch loop. (b) shows the same 5 S rRNA sequence, with the secondary structure predicted simultaneously with the *M. phlei* secondary structure using Dynalign. This predicted structure is identical to the structure determined by comparative sequence analysis (Szymanski *et al*., 2000)

Fortran 77 code for this algorithm is available for download from **ftp://ftp.ncifcrf.gov/pub/users/chen/rnaga.tar.Z**.

7. Overview of methods for multiple sequences

Each of the algorithms described here has distinct advantages. For short sequences, Dynalign provides a robust method for predicting a sequence alignment and common structure for two sequences at a time. It does not require any sequence similarity in the two sequences. Dynalign, however, does not scale well to sequences of over a couple of hundred nucleotides long. For longer sequences with low sequence similarity that are difficult to align on the basis of sequence only, FOLDALIGN can be used to find common pairs and a coarse alignment for multiple sequences. Alternatively, the genetic algorithm also provides a computationally tractable means of finding a common structure and the associated alignment for multiple sequences. ConStruct provides a graphical user interface to adjust sequence alignments manually and could, for example, take the predicted alignment from the genetic algorithm or FOLDALIGN as a basis for further manual refinement. Finally, RNAalifold is the fastest method for finding a common structure in aligned sequences. It is the best choice for finding the structure common to multiple sequences that share enough similarity to be well aligned or to multiple sequences too long to be efficiently handled by other methods.

8. Summary

Many tools are currently available for the prediction of RNA secondary structure. The last 10 years have seen both an improvement in the free energy nearest-neighbor parameters and in the breadth of secondary structure prediction tools available. On average, it is reasonable to expect about 73% average accuracy at predicting base pairs for sequences less than 700 nucleotides. Furthermore, given the completion of many whole-genome projects, it should become increasingly easy to find homologous RNA sequences. The recent work in developing algorithms to predict structures common to multiple sequences promises to improve the accuracy of secondary structure prediction.

1. Ensembl

The sequencing of the human genome has been heralded as a technological milestone of similar magnitude to the first moon landing. In reality, it has taken numerous giant leaps on the part of bioinformatics to make this a truly valuable source of information. Foremost among these efforts is the Ensembl database project. Capitalizing on the natural knowledge scaffold afforded by an organism's genome, this European-based project (counterpart of the American Locuslink project) focuses on the "geno-centric" integration and analysis of genomic data. By providing researchers with an elegant bioinformatics framework upon which to visualize, analyze, and administer genomic information, Ensembl has established itself as a key player in genomic-based discovery.

1.1. Access and availability

Ensembl is primarily accessed as an interactive web service, available at **http://www.ensembl.org** (Birney *et al*., 2004a). The system is installed globally in both industry and academia, on numerous platforms. Such wide acceptance has been facilitated by its development as an open-source portable software system that can be freely downloaded in its entirety or as individual components, including the website and analysis pipeline. The production code is available via FTP while live development code is available via a CVS server. The system is based on a MySQL relational database (*see* Article 109, **Relational databases in bioinformatics**, Volume 8) and a series of reusable bioperl modules. While primarily coded in Perl (*see* Article 104, **Perl in bioinformatics**, Volume 8 and Article 112, **A brief Perl tutorial for bioinformatics**, Volume 8), some extensions exist in C, as do alternative graphical user interfaces coded in Java.

Upon accessing the Ensembl website, biologists are greeted with the Ensembl genome browser. This page provides introductory information, a download section,

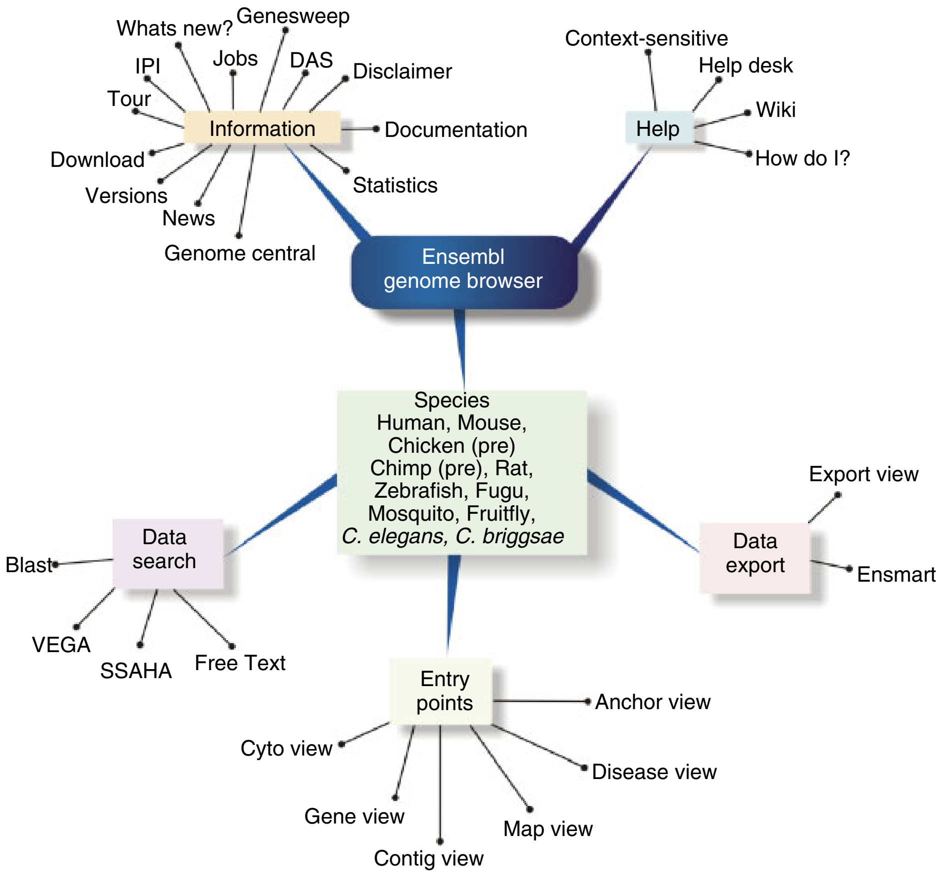

Figure 1 Map of the Ensembl website, available at **http://www.ensembl.org**

and most importantly, access to the individual species sections (see Figure 1 for a more detailed map). The latter acts as the most direct point of entry to a given organism's genomic information. At the time of writing (Ensembl v26), some 12 genomes are readily available for analysis, though the Cow and Dog genomes exist in a so-called Pre-Ensembl state. As full annotation of a genome takes some weeks to complete, Pre-Ensembl was conceived to provide users with immediate access to newly released genome assemblies. Pre-Ensembl is also available via a separate website (**http://pre.ensembl.org/**) with limited functionality.

1.2. Genome annotation

The annotation of both known and novel predicted genes in genomic DNA is the primary forte of the Ensembl system. The gene build method works on the premise that the incorporation of all available evidence is necessary for gene prediction. As such, the process uses a wide range of methods, including ab initio gene predictions, homology, and HMMs (hidden Markov models) (*see* Article 98, **Hidden**

Markov models and neural networks, Volume 8) and proceeds in a series of three steps. First, the "best in genome" positions for all known human proteins from SPTREMBL (Bairoch and Apweiler, 2000) are identified using *pmatch*, a fast but empirical protein to DNA matcher developed by Richard Durbin (unpublished). Subsequent refinement of the gene model using genewise (Birney *et al*., 2004b) is complimented by alignment of the UTRs from full-length cDNAs. In the second step, paralogous and orthologous proteins are aligned to the genome to develop a set of novel human genes. This is complimented in the final step by the HMM-based gene prediction program genscan (Burge and Karlin, 1997) that is used to generate a set of peptides, which if confirmed by homology to proteins, mRNA, and UniGene clusters, are assembled into genes. The resulting human genes have stable identifiers beginning with ENSG, while transcripts begin ENST, exons begin with ENSE, and translations begin ENSP.

Accessing information about a particular organism's genome is as simple as selecting that organism's name from the entry page of the Ensembl genome browser. A variety of alternate views for each organism are available. Perhaps the simplest is the *mapview*, which provides a cytogenetic map and associated markers for a particular chromosome, and also displays feature distribution plots such as known genes v's total genes, SNP's, and %GC content. Selection of a particular band leads one into the more detailed *contigview*. This view is perhaps the most useful, allowing one to scroll along entire chromosomes, while providing detailed views of the features within a selected region. These features are derived from external data sources such as genetic markers, OMIM genes, HUGO gene names with links to the source databases. The user can also control which features are displayed and dynamically integrate external annotation sources (e.g., DAS; see below) including their own. A so-called basepair level panel has also been added to the *contigview*, showing nucleotide, six-frame amino acid translation, and restriction enzyme site features. SNP information is also available, as is the labeling of syntenic blocks.

Other more specific views include *geneview*, which displays information about individual genes with transcripts and gene models and *proteinview*, which shows information about individual gene translations and includes functional annotation from InterPro. At this level, the ability to search for similar sequences is a useful feature, and Ensembl developers have thus provided users with the ability to search against the entire human genome sequence, predicted gene datasets, trace data, and whole genome assembly datasets, using the BLAST (*see* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7) and SSAHA algorithms. SSAHA is a software tool for very fast matching and alignment of DNA sequences.

Ensembl also caters for comparative genome analysis. Three types of comparative analyses are routinely performed together with gene identification for each new assembly. These include fine-grained DNA-DNA alignments (performed using the exonerate algorithm followed by BLASTN), orthologous protein information (using BLASTP), and large-scale synteny analysis. Synteny information is made available via the *syntenyview* interface. An alternative JAVA-based genomic viewer called *Apollo* (Lewis *et al*., 2002), developed jointly by Ensembl and the Berkeley *Drosophila* genome project, can be used to view both synteny and contig information alike.

1.2.1. DAS

Given that genome annotation is a task far too demanding for any single initiative, Ensembl developers have embraced the so-called distributed annotation system (DAS) to help bridge the gap (Dowell *et al*., 2001, **http://www.biodas.org**). DAS is a client-server system in which a single client integrates information from multiple servers, enabling a single computer to gather, collate, and display annotations in a single view. The Ensembl *contigview* can be configured to act as a DAS client for users who want to view annotation from human genome DAS servers without setting up third-party clients. Ensembl also makes its annotation data available (**http://servlet.sanger.ac.uk:8080/das/**) using the biojava DAS server DAZZLE (**http://www.biojava.org/**) for users with third-party DAS clients. The Apollo genome browser has also been extended to display data from DAS servers.

1.3. Other noteworthy features

1.3.1. EnsMart

EnsMart is Ensembl's data-mining toolset, developed as a generic data warehousing solution for efficient querying of large biological datasets and integration with third-party data and tools. EnsMart contains a "query builder" interface that allows users to specify genomic regions and then refine results using a variety of parameters including expression, disease association, and allele frequency data. Results can then be retrieved in a variety of output formats including HTML, Excel, and plain text.

1.3.2. Vega

The Vega website (**http://vega.sanger.ac.uk/**) provides access to a single database of curated annotation of vertebrate genomes collected from a number of annotation groups. Vega strides to provide consistent high-quality curation of finished vertebrate genomic sequence.

2. UniProt (Swiss-Prot, TrEMBL, PIR-PSD)

2.1. History

The Swiss-Prot Protein Knowledgebase is an annotated protein sequence database established in 1986 by Amos Bairoch at the Department of Medical Biochemistry of the University of Geneva in Switzerland. Since 1987, this has been a collaborative effort with the European Molecular Biology Laboratory (EMBL) in Heidelberg, Germany. Today, Bairoch's team is affiliated with the Swiss Institute of Bioinformatics (SIB) and the EMBL activities are carried out at the European Bioinformatics Institute (EBI) in Rolf Apweiler's group.

The goal of Swiss-Prot was always that each entry should be thoroughly analyzed and annotated by biologists to ensure a high standard of annotation and to maintain

the quality of the database. Because of the vast amount of sequences coming in from genome sequencing projects, the time-consuming task of manually curating sequences became a real challenge in the mid to the end of the 90s. As a solution to this problem, the EBI group created a complement to the Swiss-Prot database: the TrEMBL (Translation of EMBL nucleotide sequence database) protein sequence database. TrEMBL initially consisted of computer-annotated entries derived from the translation of all coding sequences (CDS) in the DDBJ/EMBL-Bank/GenBank nucleotide sequence database, except for those already included in Swiss-Prot. Because of the automatic procedure, it was possible to deliver sequences available as quickly as possible and to maintain the high-quality standard in the Swiss-Prot database.

In 1996, the Swiss-Prot databases went through a financing crisis (**http://www.expasy.org/sprot/crisis96/**) and it became clear that the only feasible solution to this problem was to obtain additional funds through the payment of yearly license fees by nonacademic users. Both SIB and EBI founded a new company, Geneva Bioinformatics (GeneBio), that acts as their representative for the purpose of concluding the necessary license agreements and levying the fees. This licensing setup was in place till January 2005, when the data again became freely available to all entities. This was possible because of the funding for the UniProt consortium by the U.S. National Institutes of Health, totaling US$ 15 million over three years.

In 2002, the SIB, the EBI, and the Protein Information Resource (PIR) group at the Georgetown University Medical Center and the National Biomedical Research Foundation joined forces as a consortium to merge the three coexisting protein databases Swiss-Prot, TrEMBL, and PIR-PSD. The resulting UniProt (Universal Protein Resource) (Apweiler *et al*., 2004) database is now the world's most comprehensive catalog of information on proteins and is the central repository of protein sequence and function.

The consortium's primary mission is to maintain a "high-quality database that serves as a stable, comprehensive, fully classified, richly and accurately annotated protein sequence knowledgebase, with extensive cross-references and querying interfaces freely accessible to the scientific community" (Apweiler *et al*., 2004).

2.2. *Access and availability*

UniProt is primarily accessed as an interactive web service, available at **http://www.uniprot.org**. The server is mirrored at the EBI, the Swiss Institute of Bioinformatics, and the Georgetown University and allows searching of the databases using a simple text query as well as using a protein sequence as a query. Additional tools such as multiple sequence alignment algorithms, batch retrieval features, and other useful links are provided. The databases can be downloaded via the comprehensive download center as flat files, FASTA-formatted files or XML files.

2.3. *Database structure*

The UniProt databases are designed as a three-database layer, each optimized for different uses as follows.

- The UniProt Archive (UniParc) provides the stable nonredundant sequence collection by storing the complete information of publicly available protein sequence data. It collects sequences from many different sources, including Swiss-Prot, TrEMBL, PIR-PSD, EMBL, Ensembl, PDB, and others. UniParc stores each unique sequence only once and assigns a unique UniParc identifier and provides cross-references to the source databases. One important feature is the sequence versioning, which is incremented each time the underlying sequence changes. In that way, one can keep track of sequence changes in all source databases.
- The UniProt Knowledgebase (UniProt) provides the central database of protein sequences. It is a curated, added value protein sequence database that provides a high level of annotation, a minimal level of redundancy, and high level of integration with other databases. The UniProt Knowledgebase consists of two sections: Swiss-Prot – a section containing manually annotated records with information extracted from literature and curator-evaluated computational analysis, and TrEMBL – a section with computationally analyzed records that await full manual annotation.
- The UniProt NREF databases (UniRef) provide nonredundant data collections based on the UniProt knowledgebase in order to obtain complete coverage of sequence space at several resolutions. It combines closely related sequences into a single record to speed searches.

3. Swiss-Prot

The Swiss-Prot database always distinguished itself from other protein databases by four distinct criteria as follows.

3.1. Annotation

Typically, in sequence databases people distinguish between the core data and the annotation of the sequence. The core data consists of the sequence data itself, the citation information, and the taxonomic data. The annotation of a sequence typically describes many different aspects of the protein. Typically, this includes the function description, posttranslational modifications, domain structure, and other secondary and tertiary structure features as well as homology relationships to other proteins and associations to known diseases. This annotation is periodically updated, and external experts have been recruited to send comments and updates.

3.2. Minimal redundancy

In Swiss-Prot, data belonging to one sequence are merged into one entry. If conflicts exist between various sequencing reports, they are indicated in the feature table of the corresponding entry. In this way, the redundancy is kept to a minimum already at the creation of a new entry.

3.3. Integration with other databases

One of the predominant features in Swiss-Prot is the comprehensive cross-linking to other databases. This includes the basic three different sequence-related databases (DNA, protein, and protein 3D structure) but extends to a broad range of specialist databases. Currently, Swiss-Prot cross-links to more than 50 different other databases (Table 1).

3.4. Documentation

Swiss-Prot is distributed with a large number of documentation files, and numerous additional information files are provided and continuously added. The most important files are the user manual, the release notes, and the forthcoming changes. The documentation provides important information about the use and interpretation of the content, which becomes especially important if one tries to extract information for statistics or data mining purposes. The references Karp *et al*. (2001), Apweiler *et al*. (2001), and Junker *et al*. (1999) are especially useful in this respect.

3.5. Structure of a typical entry

The entries in the UniProt knowledgebase are readable by human readers as well as by computer programs. Each entry is composed of lines, which start with a two-character line code followed by their specific content line(s) (Figure 2).

Table 1 The relationships (cross-references) between Swiss-Prot and some biomolecular databases

Topic	Cross-references to other databases
Sequence	EMBL, PIR
Structure	HSSP, PDB
Domains, families, sites	HAMAP, InterPro, PIRSF, Pfam, PRINTS, ProDom, PROSITE, SMART, TIGRFAMs
Posttranslational modification	GlycoSuiteDB, PhosSite

Specialist Review

Hidden Markov models and neural networks

Stefan C. Kremer
University of Guelph, Guelph, ON, Canada

Pierre Baldi
University of California, Irvine, CA, USA

1. Introduction

The development of high-throughput technology (*see* Article 24, **The Human Genome Project**, Volume 3) in the life sciences over the past 15 years has led to an unprecedented expansion in the amount of biological data that has been collected across a broad range of fields and organisms. This explosion in the availability of data has created a need for computer analysis techniques that can be used to keep up with the tasks of labeling, identifying, categorizing, postprocessing, and making predictions about this new corpus of information. Some of the challenges of developing tools to analyze the data are exacerbated by the noise and variability often present in biological data, our incomplete understanding of biological processes and systems, and insufficient computing power that prevents large-scale simulations of atomic and molecular interactions.

One potential approach to this dilemma lies in the application of machine learning (Baldi and Brunak, 2001). Machine learning approaches use example data to automatically extract statistically relevant information that can be used for predictions. The advantages of machine learning approaches include: that it is less necessary to understand the underlying principles, that higher-level approximations can be derived in place of explicit derivations, and that new problems can sometimes be approached without having to build a brand-new system from scratch.

Two popular adaptive systems in the machine learning community that have been applied to bioinformatics are hidden Markov models (HMMs) and artificial neural networks (ANNs). HMMs, originally developed for other applications such as speech recognition, are generative, probabilistic models of sequential information. In an HMM, an observed sequence is modeled as being the stochastic result of an underlying unobserved random walk through the hidden states of the model. The parameters of an HMM are the transition probabilities between the hidden states and the symbol emission probabilities from each hidden state (*see* Article 17, **Pair hidden Markov models**, Volume 7).

ANNs, originally inspired by high-level models of biological neuronal networks, consist of networks of simple processing units, where the output of a typical unit is computed by applying a nonlinear (sigmoidal) function to the weighted average of its inputs. The parameters of an ANN are the "synaptic" weights associated with each connection. Optimization algorithms, such as gradient descent in error space, are used to adapt the parameters of HMMs or ANNs over a set of training examples to exhibit a desired behavior.

Both HMMs and ANNs have been extensively applied to problems in the domain of bioinformatics (Baldi and Brunak, 2001). This review will summarize a few examples of such applications and thus provide the reader with some insights into the types of problems to which these computational methods can be applied, their relative strengths and weaknesses, and an understanding of the issues involved in putting them into practice.

2. Hidden Markov models

HMMs have a long tradition in automated speech processing. Their ability to deal with sequences that can be stretched or compressed, that contain noise, and that vary over time makes them uniquely suited to applications in speech processing. Some of these properties also apply to genomic sequences.

To be precise, a first-order HMM consists of a set of states, {0,1,2,3 ... }, a set of symbols X, an $(L + 2) \times (L + 2)$ matrix of transition probabilities, A, and a matrix of emission probabilities, E. For simplicity, here we label both the start and end state as 0. Each element in the matrix of transition probabilities, a_{kl}, represents the probability that a given state follows a given previous one along a path π:

$$a_{kl} = P(\pi_i = l|\pi_{i-1} = k) \tag{1}$$

The probability of emitting a particular symbol, b, while in a particular state, k, is

$$e_k(b) = P(x_i = b|\pi_i = k) \tag{2}$$

Together, these definitions allow us to compute the probability of a given path occurring and a given set of symbols being emitted:

$$\mathrm{P}(x, \pi) = a_{0\pi_1} \prod_{i=1}^{L} e_{\pi i}(x_i) a_{\pi_i \pi_{i+1}} \tag{3}$$

Finally, the probability of a given sequence x is the sum of the probabilities $P(x,\pi)$ over all the paths π that are consistent with that sequence. It is often useful to try to infer the most probable cause of an observed sequence. That is, given a sequence, to compute the most probable state path.

$$\pi^* = \underset{\pi}{\arg\max} \quad P(x, \pi) \tag{4}$$

This can be accomplished by dynamic programming, using the well-known Viterbi algorithm. This algorithm operates by iteratively computing the maximum probability of being in each possible state after each symbol in the sequence of interest. For the first step, there is only one way to get to each state (from the start state), so the maxima are computed over one previous state. In subsequent steps, however, each of the states in the HMM can be a potential previous state, so the maximum probability of being in any given state must be computed over all possible prior states. By recording the prior state that gave the maximum likelihood at each step, it is possible to compute the most probable sequence. This is also called aligning a sequence to a model. A similar dynamic programming recursion can be used to compute the probability $P(x)$ of a sequence, without having to sum over an exponentially large number of possible paths. Similar dynamic programming principles (e.g., the Baum–Welch or EM algorithm) can be applied during training to iteratively modify the matrices A and E to maximize the likelihood of the sequences in the training set. A very simple idea for training, which works quite well in practice, consists in computing the most likely path for each training sequence using the Viterbi algorithm and increasing all the transition and emission probabilities along each optimal path. Details of the algorithms are found in the references.

HMMs are used extensively in bioinformatics applications in tasks ranging from multiple alignments, to protein family modeling and classification (*see* Article 78, **Classification of proteins into families**, Volume 6), to pattern discovery, and to gene finding (Baldi *et al*., 1994; Krogh *et al*., 1994; Durbin *et al*., 1998; Baldi and Brunak, 2001).

3. Artificial neural networks

In ANN models, the output out_i of neuron i is described by

$$out_i = f_i\left(\sum_j w_{ij} out_j\right) \tag{5}$$

where f_i is the transfer function of the neuron and w_{ij} is the synaptic weight of the connection from neuron j to neuron i. It is clear today that the neurons used in ANN models are orders of magnitude simpler than their distant biological cousins. In spite of this apparent simplicity, ANNs have been quite successful as a machine learning approach to pattern recognition, and function approximation (e.g., classification or regression). A typical neural network processes inputs in the form of vectors and computes outputs, also in vector form. Many applications are based on feedforward architectures containing no directed cycles, where the neurons are organized into input, output, and one or more hidden layers. Recurrent or recursive networks are obtained when directed cycles of connections are allowed, for instance, by feedback of output layer onto input layer. One important theoretical property of neural networks is their universal approximation properties – basically,

any reasonable function can be approximated to any degree of precision by a neural network (Hornik *et al*., 1989). While this existence theorem is reassuring, the real problem is to find a reasonable architecture for a given problem in a reasonable time. This is the issue addressed by machine learning methods.

In addition to the ability to compute almost arbitrary output vectors in response to their inputs, ANNs include an automated method for updating the parameter arrays. This is typically done by some optimization algorithm, the most popular being gradient descent, also known as back-propagation and the generalized delta rule (Werbos, 1974; Rumelhart *et al*., 1986). In this approach, an error measure is used to compute the error of the network in response to one or more example patterns (consisting of an input and a target output). Then, the gradient of that error is computed to determine the direction of greatest descent in weight space. By making repeated changes in the weights in the direction of this gradient, a local minimum can be found. While it is possible that this local minimum does not represent a global minimum, often, this local minimum represents an adequate approximation to the function that one wants to learn.

A feedforward ANN generates one output for every input and contains as its only (long-term) memory the parameter matrices that remain static after the training process is completed. For some problems, however, it is desirable to process a sequence of inputs, or produce a sequence of outputs. This is valuable when the input data is distributed in time (i.e., the inputs in the sequence arrive over a period of time) or, for instance, when there is a shift invariance in the relevant input pattern. In this context, shift invariance refers to the notion that an input pattern that occurs within a sequence should have the same effect regardless of its position within the said sequence. Recurrent networks address this problem by including a different kind of memory, short-term memory. This short-term memory is implemented by introducing feedback in the circuits (Kolen and Kremer, 2001). While a feedforward network can be built to simply take a very long sequence as its input, this type of processing cannot produce the kinds of parsimonious solutions that recurrent networks can. More generally, a special kind of recurrent network, called a *recursive ANN architecture*, can be built by combining ANNs with the theory of graphical models (Baldi and Pollastri, 2003).

ANNs have been used extensively in a variety of bioinformatics applications ranging from the detection of signal peptides (Nielsen *et al*., 1997) to the prediction of protein structural features such as secondary structure, relative solvent accessibility, and contact maps (Rost and Sander, 1994; Baldi and Brunak, 2001; Baldi and Pollastri, 2003).

4. Hidden Markov models for identifying sequence families

A standard application of HMMs to bioinformatics is to model protein families (*see* Article 78, **Classification of proteins into families**, Volume 6). The idea is to build an HMM for a given family of sequences that captures the commonalities and differences of the sequence in a probabilistic fashion. Such a model can then be used to produce multiple alignments, to evaluate a new sequence, and determine whether the new sequence belongs to the family represented by the model.

As an example, we consider the case of globins, as proposed in Durbin *et al.* (1998). Globins, of course, are oxygen-binding proteins and include hemoglobins, myoglobins, leghemoglobins, and flavohemoproteins. This commonality of function exhibited across a huge range of organisms (including plants, bacteria, and both vertebrate and invertebrate animals) makes them a particularly interesting and diverse family of molecules.

To model the globin family with an HMM, we can first start from a multiple alignment of a set of known globin sequences. From this alignment, it is possible to construct an HMM with a very specific arrangement of states, as shown in Figure 1.

This HMM has the following properties. S represents the start state of the HMM and has no associated emissions. E represents the end state of the HMM and also has no associated emissions. M_1 represents the first column in the alignment that does not contain mostly gaps. Its emission probabilities are set to match the frequency of the various residues in the column of the alignment. Similarly, M_i represents the ith column in the alignment that does not contain mostly gaps and has emission probabilities corresponding to the ith nongap column's residue frequencies. Thus, the central chain of M_i's represents the most typical residue sequences.

The states labeled I_i represent extra residues inserted into atypical sequences and can be visited (and revisited via the recurrent arrows) in addition to the sequence of M_i's. Each state, I_i, has associated emission probabilities for the "extra" residues that do not occur in the more typical sequences. The states labeled D_j represent deletions of residues from the typical sequences. There are no emissions associated with the D_j states, and since these states are visited instead of M_i states, they effectively delete a residue from the typical sequence. Thus, in short, the M chain represents the match states and it is flanked by a chain of insert and delete states to allow insertions and deletions at each position in the sequence. For this reason, unusually long sequences will tend to pass through more I states, while unusually short sequences will tend to pass through more D states. This provides an elegant solution to the problem that not all sequences have the same length and that even sequences with the same length can be aligned quite differently.

The task of assigning emission and transition probabilities is quite straightforward, based on the frequencies of the residues in the alignment and the frequency of gaps. It should be noted, however, that if raw frequency values were used, new

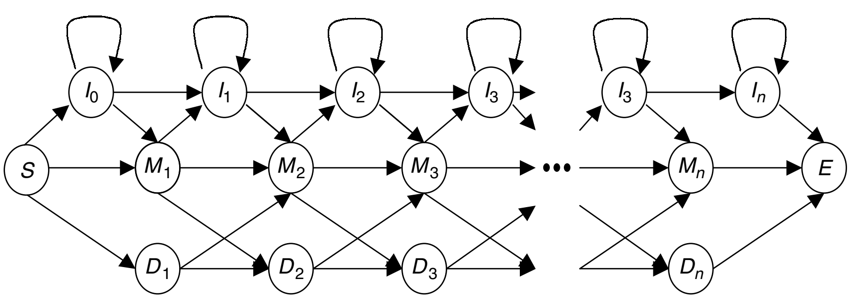

Figure 1 Profile HMM consisting of a start state (S), an end state (E), and sequences of main or match states (M), insert states (I), and delete states (D). (Optionally, there can be D-I and I-D connections, but these are omitted in this diagram for simplicity.)

globins that happened to contain a residue not found in any of the sequences in the training set would automatically be associated with a probability of zero. To avoid this problem, pseudocounts can be added to the frequencies to allow for some tolerance of deviance.

If an initial multiple alignment is not available, the HMM parameters can still be estimated using the dynamic programming learning algorithms discussed above.

A trained HMM can be used in several ways. First, we can align any sequence to the HMM by computing its Viterbi path and also its likelihood. A multiple alignment of globin sequences is immediately derived by aligning their corresponding Viterbi paths.

Second, we can use the likelihood score of a sequence to discriminate between globin and nonglobin sequences and search large databases. Finally, conserved patterns of residues associated, for instance, with structural or functional motifs can be detected from the HMM parameters or from the corresponding multiple alignment.

The use of HMMs for protein classification can be further enhanced by building libraries of HMM models associated with different protein families. There are now fairly comprehensive libraries of preconstructed HMMs for many protein families, available for download on a few websites. The most widely used is the Pfam database (Bateman *et al*., 2004; *see also* Article 86, **Pfam: the protein families database**, Volume 6). As of January 2004, this database contained more than 7200 families and covered an estimated 75% of all protein sequences. Rfam is a similar database for RNA (Griffiths-Jones *et al*., 2003).

5. Protein prediction with recursive networks

Many ANN applications use a simple feedforward network with a fixed window size input. These architectures are suitable, for instance, for pattern recognition problems in which the scale of the patterns to be detected falls within the size of the window. Many problems, however, are characterized by patterns occurring at multiple length scales that do not fall naturally inside a single window size. In this sense, HMMs are more elastic than simple feedforward ANNs because they can accommodate input sequences of variable length. However, this is not an intrinsic limitation of ANNs since recursive architectures can be built that can accommodate inputs of variable structure, size, and dimensions. Here, we give an example of a recursive network for the prediction of 2D protein contact maps taken from Baldi and Pollastri (2003).

Given a protein sequence, the goal is to produce a topological representation of its structure in the form of a contact map. The contact map is a two-dimensional, symmetric, binary matrix, representing the 3D proximity of objects (atoms, amino acids, secondary structure elements) associated with a sequence. Typical thresholds used to assess proximity at the amino acid level are in the 6–12-Å range.

A recursive architecture to tackle this task consists of five feedforward ANNs. A feedforward network N_O that computes the probability of contact $O_{i,j}$ between amino acids i and j as a function of the input vector $I_{i,j}$, and four, hidden, contextual vectors, $NW_{i,j}$, $NE_{i,j}$, $SW_{i,j}$, $SE_{i,j}$ associated with each one of the cardinal corners (Figure 2), and four feedforward networks associated with each one of the four

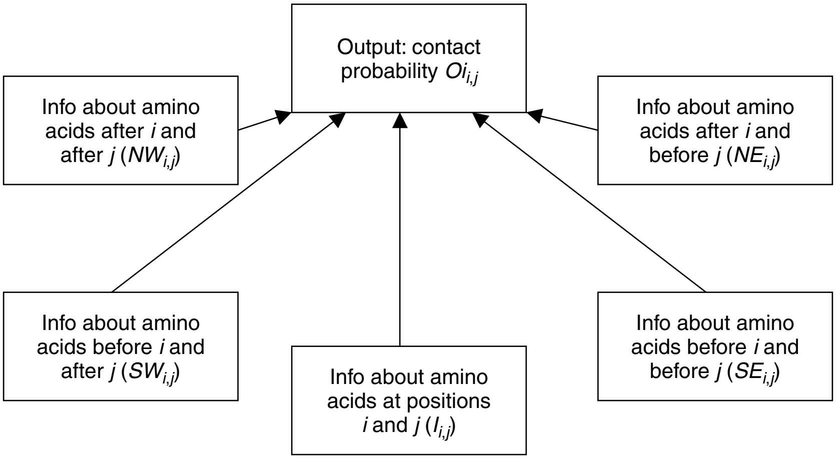

Figure 2 Organization of contact map output prediction

cardinal directions to compute each of the four hidden context vectors. The N_{NW} network, for instance, computes the $NW_{i,j}$ vector as a function of the input vector, $I_{i,j}$, and the neighboring vectors, $NW_{i+1,j}$ and $NW_{i,j-1}$, in the NW lattice. Thus,

$$\begin{aligned} O_{i,j} &= \mathrm{N}_O(I_{i,j}, NW_{i,j}, NE_{i,j}, SW_{i,j}, SE_{i,j}) \\ NW_{i,j} &= \mathrm{N}_{NW}(I_{i,j}, NW_{i+1,j}, NW_{i,j-1}) \end{aligned} \tag{6}$$

and *mutatis mutandis* for the other cardinal directions. The key assumption is that of stationarity, also called weight sharing in the ANN literature, whereby the N_O network is the same across all *i,j* positions, and similarly for the networks that compute lateral contextual information. In the simplest formulation of this approach, the input vector $I_{i,j}$ encodes the identity of the two amino acids at positions i and j in the primary sequence using unary notation, that is, an amino acid is encoded by a 20-dimensional sparse vector containing 19 zeros and a single one. In practice, significantly more complex input vectors are used that contain information about a window of amino acids around i and j, plus information about homologous sequence (profiles) as well as correlated mutations and structural features, such as secondary structure and relative solvent accessibility.

This system takes an amino acid sequence of an arbitrary length, N, as its input and produces an $N \times N$ matrix of contact/noncontact probability values as outputs. The stationarity approach results in a recursive ANN architecture, whereby contact inference is made in the same way at each 2D location. In principle, the decision at position i can be affected by information coming from any other position j through the lateral propagation in the cardinal planes. Note that each one of the five feedforward ANNs can itself comprise its own hidden layers and variable numbers of artificial neurons and connections. The weight-sharing assumption, however, allows us to keep the total number of parameters of the model under reasonable control. Typical models used in contact map applications have several thousand parameters.

The parameters of these recursive architectures can be adjusted using a gradient descent approach, which generalizes the back-propagation algorithm for simple feedforward network. Using this algorithm, a dataset of proteins from the Protein Data Bank (*see* Article 71, **The Protein Data Bank (PDB) and the Worldwide PDB http://www.wwpdb.org**, Volume 7) with known structures can be used to adapt the parameters of the networks. Trained networks can be used to predict contact maps for novel proteins and, in turn, contact maps can be used to predict 3D structures. While training can take several days, once trained, the recursive ANNs can predict contact maps very rapidly on a genomics scale. The resulting contact map predictor is a component of the SCRATCH protein structure prediction Web server, which is publicly available through **http://www.igb.uci.edu/servers/psss.html**

6. Conclusion

In this contribution, we have surveyed the application of ANNs and HMMs to problems in bioinformatics. We have described two protein applications in some detail: HMMs to model families and recursive ANNs to predict contact maps. We have obviously only scratched the surface of what defines these techniques, their strengths and weaknesses, how they are applied, and the results that can be obtained. Many more important details and statistical considerations (e.g., ensembles, cross-validation) can be found in the references.

It is important to stress that successful machine learning applications in bioinformatics must go hand in hand with a good understanding of the underlying biological principles and should not start from a *tabula rasa*. This is true not only for the design of the architecture of the learning system and the incorporation of any prior knowledge but also for the selection and processing of the training data. In most cases, training data must be preprocessed to clean up errors and noise and remove important biases. In the Protein Data Bank, for instance, HIV protease structures are highly overrepresented because of the emphasis on AIDS in medical research and funding. Such biases must be removed from any training set aiming at sampling the universe of protein structures as uniformly as possible. This is done, for instance, by aligning all sequences to each other and removing those that are redundant. It is also critical to match the number of free parameters in the models to the problem complexity and the data set size. Too many free parameters can lead to overfitting. Luckily, this is typically not the major problem in bioinformatics applications, given the overabundance of data.

As the volume of biological data collected and accessible on-line continues its exponential growth, machine learning will play an ever-greater role in the extraction and mining of biological knowledge.

1. Background

The goal of protein structure prediction by threading is to align a protein sequence correctly to a structural model. This requires choosing both the correct structural model from a library of models and the correct alignment from the space of possible sequence-structure alignments. Once chosen, the alignment establishes a correspondence between amino acids in the sequence and spatial positions in the model. Assigning each aligned amino acid to its corresponding spatial position places the sequence into the three-dimensional (3D) protein fold represented by the model. Typically, the model represents only the spatially conserved positions of the fold, often the protein core, so producing a full-atom protein model would require further steps of loop placement and side-chain packing. Protein threading has a role in protein structure prediction that is intermediate between homology modeling (*see* Article 70, **Modeling by homology**, Volume 7) and ab initio prediction (*see* Article 66, ***Ab initio*** **structure prediction**, Volume 7). Like homology modeling, it uses known protein structures as templates for sequences of unknown structure. Like ab initio prediction, it seeks to optimize a potential function (an objective or score function) measuring goodness of fit of the sequence in a particular spatial configuration. Threading is the protein structure prediction method of choice when (1) the sequence has little or no primary sequence similarity to any sequence with a known structure and (2) some model from the structure library represents the true fold of the sequence.

Protein threading requires (1) a representation of the sequence, (2) a library of structural models, (3) an objective function that scores sequence-structure alignments, (4) a method of aligning the sequence to the model, and (5) a method of selecting a model from the library. Following the initial conception of the threading approach to protein structure prediction (Bowie *et al*., 1991; Jones *et al*., 1992),

there have been very many different approaches to these problems, of which this chapter can present only a few general themes.

2. Representation of the query sequence

It is widely accepted that significantly similar protein sequences also adopt a similar 3D structure. The Paracelsus Challenge demonstrated the design of a protein sequence with 50% sequence identity to a known protein but a different 3D structure (Jones *et al*., 1996), but when natural evolution produces similar protein sequences their protein structures generally are similar as well. Thus, in naturally occurring proteins, sequences that are similar to the query sequence carry useful information about its 3D structure. A multiple-sequence alignment centered on the query sequence reflects sequence variability within the protein family to which the query sequence belongs. Most modern threading algorithms exploit this fact (Jones, 1999; Fischer, 2000; Kelley *et al*., 2000; Panchenko *et al*., 2000; Rychlewski *et al*., 2000; Karplus and Hu, 2001; Skolnick *et al*., 2003).

The query sequence is often represented by a sequence profile, **P**, where the element $P_j = P(A|j)$ is a vector giving a probability distribution over the 20 amino acids at sequence position j. In this notation, a single query sequence has a profile with 1 for the original amino acids and 0 otherwise. The sequence profile is typically constructed from the search of nonredundant databases of proteins (e.g., at NCBI) and sequences are aligned using multiple-sequence alignment programs such as CLUSTAL (Higgins *et al*., 1996) or PSI-BLAST (Altschul *et al*., 1997). Some threading methods also include an independent prediction of the secondary structure (SS) (*see* Article 76, **Secondary structure prediction**, Volume 7) or other derived information as part of the sequence representation. In such cases, the query is represented as two independent vectors $P_j = \{P(A|j), P(SS|j)\}$, where SS might be helix, strand, or coil, a more detailed set of secondary structure assignments, or other information.

3. Representation of protein structure models

What is a model of protein structure? Protein structure is fully determined by the 3D coordinates of all non-hydrogen atoms. For threading, the 3D coordinates are reduced to more abstract representations of protein structure. Typically, structural core elements are defined by the secondary structure elements, α-helices and β-strands, usually with side chains removed. Among proteins with similar structures, large variations occur in the loop regions connecting the structural elements. In consequence, loop lengths, loop conformations, and loop residue interactions are rarely conserved, and often the loop residues are not represented explicitly in the structural models.

The main distinction among threading approaches is the choice of the structure model representation. Threading algorithms fall into two main categories that depend on the protein structure representation they use:

1. In the first category, a protein structure is represented as a linear model.
2. In the second category, a protein structure is represented as a higher-order model.

In a linear representation, the protein structure is modeled as a chain of residue positions that do not interact. In a second-order representation, the model also includes interacting pairs of residue positions, for example, to account for hydrophobic packing, salt bridges, or hydrogen bonding. Still higher order models have been considered to represent triples and higher multiples of interacting residue positions, but are less common.

Approaches that represent protein structure as a linear model consider each structural position in the model independently, neglecting spatial interactions between amino acids in the sequence. This allows very fast alignment algorithms, but loses whatever structural information may be present in amino acid interactions. Approaches that use higher-order models explicitly consider spatial interactions between amino acids that are distant in the sequence but brought into close proximity in the model. This potentially allows for more realistic and informative structural models, but results in an NP-complete alignment problem (Lathrop, 1994). It is known that the information content in higher-order amino acid interactions is modest, but nonzero (Cline *et al*., 2002). What effect this has in practice, and whether the increased information content compensates for the increased complexity, is a subject of some debate within the protein threading community.

3.1. 1D models of the protein structure

A 1D model of a protein structure is a sequence of states representing the residue as if embedded in a 3D structural environment. There are two distinct types of features frequently used to characterize a state, structural features, and amino acid sequence features. The structural features include the solvent exposure of a given residue, the secondary structure of the residue, and so on. The structural features may be representations of a single specific structure or (weighted) averages of structural features from multiple structures in the same family (*see* Article 75, **Protein structure comparison**, Volume 7). The sequence features may include the original amino acids observed in the structure or a sequence profile representing the multiple alignment of sequences from the protein family of the structure's native sequence.

If we denote by s a residue position in the structure (or a position from the alignment of multiple structures), then a vector of features $\mathbf{F}(s)$ describes each position. Thus, a structure model is an ordered chain of feature vectors $\{\mathbf{F}(s)\}$. The dimensionality of the feature vector depends on the specific threading approach.

The original 1D threading papers represented the feature vector as solvent exposure states, where the solvent exposure was calculated from the exposure of amino acids present in the native structure. Since then it has been recognized that, due to variations in the amino acid's size, one must use a measure of exposure that is independent of the native amino acid size. Most recent threading methods use the polyalanine representation of a structure. Solvent exposure state is determined by the solvent exposure of an alanine placed at each residue position. Some approaches vary the radii of the solvent molecule and the β-carbon.

3.2. 2D models of the protein structure

Two-dimensional models attempt to capture the contribution of interactions between pairs of residues. They begin with a 1D representation of a protein structure, and

then overlay representations of pairs of residues that are neighbors in the folded structure. In many threading methods, the pairs are represented as a contact map, where the contact can be defined by any of several methods:

Dependent on the native amino acid side-chain orientation:

1. Residues are in physical contact in the native structure, for example, if the distance between any of their atoms is smaller than a given cutoff, say 5 Å.
2. The distance between the centroids or C_β atoms of the residue side chains is below a certain cutoff.
3. The neighbors are determined by additional geometric constraints imposed by the 3D structure, for example, the C_β atoms may have to be in line-of-sight of each other. This excludes from the neighbor set pairs that can never interact, like residues on the opposite sides of an α-helix.

Independent of the native amino acid side-chain orientation:

1. Any pair separated by a given number of residues, for example, neighbors every 1, 3, or 4 residues in an α-helix, or every 2 residues in a β-sheet.
2. Any pair that has C_α closer than a cutoff value, say 7–10 Å.

Similar to the 1D representation, a pair of residue positions s and r is represented by a feature vector $\mathbf{FF}(s,r)$. The pair associated features fall into three categories:

1. 3D distance–derived features; distance between the β-carbons, distances among all other backbone atoms, distances between the centroids of side-chain positions, and so on.
2. 1D residue separation along the amino acid sequence of the native protein.
3. Structural environments of each residue in the pair like solvent exposure or secondary structure.

Definitions of the various environmental variables differ dramatically among threading approaches. The most commonly used feature for the 2D environments is the 3D distance. Typically, the distance between two atoms is partitioned into bins that are defined by a lower and upper distance threshold. In general, a similar approach can be applied to any feature that is associated with a real or integer variable. Most feature variables require binning, such as distance, solvent exposure, and 1D sequence separation.

3.3. Higher-order structural models

Third-order and higher models attempt to capture regularities of protein structure that cannot be represented by considering amino acid pairs only. For example, adjacent pairs of cysteines may form disulfide bonds, but only one disulphide bond can form among three adjacent cysteines; Godzik *et al*. (1992) used amino acid triples to represent this and related properties. The hydrophobic contact potential of Huang *et al*. (1996) is equivalent to amino acid triples, in this case used to represent the hydrophobic core. A fourth-order representation is the Delaunay tessellation, based on the vertices of irregular tetrahedral lattice (Singh *et al*., 1996; Munson and Singh, 1997; Zheng *et al*., 1997). Higher-order models suffer from the statistician's

"curse of dimensionality"; an Nth-order model must represent 20^N N-tuples. It can be difficult to parameterize the model and the objective function (below) unless reduced amino acid alphabets are used.

4. Objective function (potential or score function)

Most threading approaches do not use the physical full-atom free energy functions commonly used by macromolecular modeling software (*see* Article 74, **Molecular simulations in structure prediction**, Volume 7). Instead, most threading objective functions are determined empirically by statistical analysis of the 3D data deposited in the Protein Data Bank (PDB) (*see* Article 71, **The Protein Data Bank (PDB) and the Worldwide PDB http://www.wwpdb.org**, Volume 7). Thus, they are often referred to as *empirical potentials* or *knowledge-based potentials*. In the case of nonlinear structural models, another common name is *contact potentials*, reflecting their origin in analysis of contacts between atoms or residues in crystal structures. Many approaches augment empirical potentials with other terms thought to be important, for example, contributions from loop regions if the structural model contains only the protein core.

A great many different approaches have been explored. As examples, the hydrophobic contact potential of Huang *et al*. (1996) reflects packing in the hydrophobic core using only two residue classes, hydrophobic and polar, and is remarkable for its explanatory power given its simplicity and near absence of adjustable parameters. Maiorov and Crippen (1994) used linear programming to enforce a constraint that the native threading scores lower than others, but such approaches tend to be brittle. Bryant and Lawrence (1993) used logistic regression, based on multidimensional statistics. Boltzmann statistics is the foundation of many threading methods (Sippl, 1995). White *et al*. (1994) derived a formal probability model based on Markov Random Fields. Many other approaches have been investigated.

The most popular approach involves a negative log odds ratio between the observed and expected amino acid frequencies in a given structural environment. This yields a measure that is analogous to a physical free energy, and gives good results. Given 1D or 2D structural features F or FF defined by a specific structural library, the objective function is determined by counting amino acids with specific features in known 3D structures. The score for observing amino acid A with feature F is determined by $P(A,F)$, the probability of observing the amino acid A with the feature F in the protein structure database. Different methods apply different normalizations to the probability $P(A,F)$. The general motivation is to remove variations that do not contribute to specific sequence-structure recognition, for example, to control for the fact that some amino acids are more common than others. The score (*see* Article 67, **Score functions for structure prediction**, Volume 7) for amino acid A when found in feature F is

$$S(A, F) = -\log \frac{P(A, F)}{N(A, F)} \tag{1}$$

Here $N(A,F)$ is a normalization constant for A and F, typically derived from some assumed reference state or from assumptions of conditional independence.

Various choices of $N(A,F)$ have been explored, one of the simplest being $N(A, F) = P(A)P(F)$.

The same logic applies to pairs of residues, or pairs of atoms associated with residue positions. Some methods use only the amino acids while others use their respective backbone atoms and/or generalized side-chain atoms to define the 2D features of a pair of positions. For two amino acids A and B, where the feature FF is associated with the pair of positions, the score is given by:

$$S(A, B, FF) = -\log \frac{P(A, B, FF)}{N(A, B, FF)} \quad (2)$$

Owing to high redundancy of the PDB, typically a database of nonredundant or representative structures is used for calculation of probabilities. An objective function is often implemented by a number of 20×1 and 20×20 matrices associated with each 1D and 2D structural feature from the feature sets $\{F\}$ and $\{FF\}$ respectively.

Once the objective function is defined and its values estimated from the current database, it is fast and straightforward to calculate the score of a given sequence-structure alignment. The alignment is a placement of amino acids from a sequence $\mathbf{A} = \{A_1, \ldots, A_i, \ldots, A_L\}$ into positions $\mathbf{s} = \{q, \ldots, r, \ldots, s\}$ from the structure model, where the model is a collection of positions and pairs of positions as discussed above. A threading (alignment) is a (possibly partial) map t of sequence indexes i to model indexes, $t(i)\epsilon\mathbf{s}$. Most threading algorithms impose an ordering constraint of mapping increasing sequence indexes to increasing model indexes: if $i < j$, then $t(i) < t(j)$. In principle, relaxing such a constraint would allow threading to recognize/predict a structural topology that is not yet present in a database of known structures, but this is not usual in practice. The score S of the sequence-structure alignment $t(\mathbf{A}) = \{A_1^{t(1)}, \ldots, A_i^{t(i)}, \ldots, A_L^{t(L)}\}$ is given by:

$$\begin{aligned} S(t(\mathbf{A})) = &\sum_{F\in\{F\}} w_F \sum_i S\left(A_i^{t(i)}, F(t(i))\right) \\ &+ \sum_{FF\in\{FF\}} w_{FF} \sum_{\{i,j\},i<j} S\left(A_i^{t(i)}, A_j^{t(j)}, FF(t(i), t(j))\right) \end{aligned} \quad (3)$$

where the sum over different feature categories $\{F\}$, $\{FF\}$ often includes different weights. $F(t(i))$ is the feature of the model position $t(i)$ and $FF(t(i),t(j))$ is the feature associated with a pair of model positions $t(i)$ and $t(j)$. The weights w_{F}, w_{FF}, among different feature terms are subjected to optimization in many threading approaches. One of the 1D features often included in an objective function is a gap opening and extension penalty. The gap opening and gap extension penalties are special features that can depend on the length k of the gap $w(k|F(t(i)))$ and can also depend on the features of the structural model. Many threading approaches do not allow gaps inside the core structural elements, for example, by setting the gap opening penalty to $+\infty$ for positions in the core structural elements. The gap opening and extension penalty terms imply that there are even more weights to optimize.

4.1. Methods of refining the pairwise objective function

The pairwise interaction between residues depends on both the geometric features of positions close in the 3D structure, and on the specific amino acids that are aligned to those positions. There are two methods that attempt to capture these complicated dependencies.

In the Filtered Neighbors Threading approach, the objective function is constructed specifically for each structural model (Bienkowska *et al*., 1999). Each pair of positions has its unique objective function calculated by taking a Hadamard product of two 20 × 20 matrices $S(\cdot,\cdot,FF(s,r))$ and $V(\cdot,\cdot,s,r)$. The $S(\cdot,\cdot,FF(s,r))$ matrix is the usual pairwise objective function as defined by the statistics of amino acid pairs with a given structural feature $FF(s,r)$. The $V(\cdot,\cdot,s,r)$ is a binary matrix of 0's and 1's specific to the pair of structural positions from the template. A "0" for amino acids A and B indicates that physical contact between these amino acids is not plausible when placed at respective positions in the template structure and "1" indicates that a physical contact is plausible. The plausibility of a physical contact is calculated independently of the objective function S. A number of geometrical descriptors of neighboring structural positions describe neighbor pairs. The algorithm first analyzes a set of all 3D neighbor pairs from the database of proteins and partitions the space of geometrical descriptors into regions occupied by most of the observed physical contacts and the rest of the space. Thus, any pair of neighboring positions is defined as a plausible physical contact or not depending where it is in the space of geometrical descriptors.

The approach implemented by PROSPECTOR2 iteratively constructs a pairwise objective function (Skolnick and Kihara, 2001). This algorithm uses an iterative dynamic programming approach with the pairwise objective function redefined at each iteration (see frozen approximation below). During the iteration, a sequence is threaded through the entire library of structural models. Top-scoring structures (within an empirically set score cutoff) are selected and the number of predicted contacts between sequence residues A_i and A_j is calculated as q_{ij}. If q_{ij} is greater than 3, then a "filtering" objective function is given by $V(i,j) = -\ln(q_{ij}/q^0)$, where the normalization factor is $q^0 = \sum_i \sum_j q_{ij}/L^2$. The objective function in the next iteration step is the arithmetic average of the "filtering" objective function and the original objective function $S(A_i, A_j, F(t(i), t(j)))$, if the filtering score is defined for the respective residues.

5. Aligning a sequence to a model

The goal of a threading alignment algorithm is to find an optimal match between the query sequence and a structural model among all possible sequence-structure alignments. The optimality of the match is defined by the objective function. If the objective function includes the quadratic term describing residue pairwise interactions, the general problem of finding the optimal alignment is NP-complete (Lathrop, 1994). Thus, one principal distinction among threading algorithms is determined by the objective function. The algorithms fall into three broad categories.

1. 1D algorithms that use only the information that is associated with the 1D features of the structure.
2. 1D/2D algorithms that apply the 1D search logic (objective function representation) for the optimal alignment but at various steps use the information inferred from the 2D features to redefine the objective function.
3. 2D algorithms that use the full 2D representation of the problem and deal with the higher complexity of the search space.

5.1. 1D algorithms

For one-dimensional models the sequence-structure alignment problem is analogous at an algorithmic level to sequence–sequence alignment. Given an objective function, an optimal alignment can be found using a dynamic programming alignment algorithm (Needleman and Wunsch, 1970; Smith and Waterman, 1981). This results in very fast sequence-structure alignment.

5.2. 1D/2D algorithms

The motivation in this type of algorithm is to include 2D information for its presumed greater information content, but use 1D alignment algorithms for speed. Thus, they look for an approximately optimal score, rather than the global optimum. In addition to 1D amino acid preferences, the score includes the 2D pairwise amino acid preferences. The expectation is that the inclusion of such preferences will improve the recognition of the best structural template. The algorithm of GenThreader (Jones, 1999) uses the quadratic terms of the objective function to evaluate the alignment generated by a 1D Smith–Waterman algorithm. These 2D scores together with sequence-profile similarity scores and solvation scores are the input to a neural network that assesses the confidence of the prediction. The neural network is trained on all known pairs of sequences that are known to have similar structures. The frozen approximation (Godzik *et al.*, 1992; Skolnick and Kihara, 2001) iteratively performs a 1D alignment using 2D information fixed by the previous 1D alignment step.

5.3. 2D search algorithms

All 2D threading algorithms face an alignment problem that is formally intractable, so they differ on the basis of whether they return a good approximate alignment quickly or the global optimum alignment more slowly. Gaps are typically restricted to loops or the ends of secondary structure elements in order to reduce the alignment space and because deletions and insertions are less likely in the tightly packed protein core.

The Gibbs Sampling Algorithm (Bryant, 1996) begins with a random alignment. At each step it randomly chooses a core secondary structure element C, generates all possible alternative alignments for it, calculates each new alignment score S,

chooses a new alignment with probability proportional to $\exp(-S/kT)$, and fixes C at the new location. The procedure iterates using an annealing schedule to reduce the nominal energy units kT, then picks a new random alignment and repeats. The method does not guarantee a global optimum alignment, but is very fast and gives good performance.

The divide and conquer threading algorithm (Xu *et al*., 1998) repeatedly divides the structure model into submodels, solves the alignment problem for submodels, and combines the subsolutions to find a globally optimal alignment. Dividing the model into smaller pieces means that some pairs of model positions that contribute to the pairwise score will be split between different submodels, so the cutting of a pair link is recorded and accounted for when the subsolutions are recombined.

The branch-and-bound search algorithm (Lathrop and Smith, 1996) repeatedly divides the threading search space into smaller subsets and always chooses the most promising subset to split next. Eventually, the most promising subset contains only one alignment, which is a global optimum. It relies on a lower bound on the best score achievable within each subset. An anytime version (Lathrop, 1999) returns a good approximation quickly, then iteratively improves the approximation until finally returning a global optimum alignment.

Protein threading by linear programming (Xu *et al*., 2003) formulates the threading problem as a large scale integer programming problem, relaxes it to a linear programming problem, and solves the integer program by a branch-and-bound method. It is also an optimal method.

6. Selecting a model from the library

Finding the optimal score and alignment of a sequence to a structure leaves open the question what is a likely structure of the query sequence. There are broadly two approaches to this question. The first chooses the structure on the basis of the best alignment score, usually after normalizing scores in some way so that scores from different models are comparable. The second integrates the total probability of a model across all alignments of the sequence to the model. The first approach is more popular and intuitive, though the second is better grounded in probability theory.

Unlike sequence–sequence alignment, there is no straightforward method to determine the statistical significance of the optimal score (Bryant and Altschul, 1995). The statistical significance of the score tells how likely it is to obtain a given optimal score by chance. The distribution of scores for a given query sequence and structural model depends on both the length of the sequence and the size of the model. Currently, there is no generic analytical description of the shape of the distribution of threading scores across different models and sequences, though it is well understood that the distribution of optimal scores is not normal. For gapped local alignment of two sequences, or a sequence and a sequence profile, the distribution of optimal alignment scores can be approximated by an extreme value distribution. Fitting the observed distribution of scores to the extreme value distribution function has been applied by profile threading method FFAS (Rychlewski *et al*., 2000). Some profile-based methods approximate the distribution of scores by a normal

distribution and calculate Z-scores. The Z-scores are calculated with the mean and standard deviation of the scores of a query sequence with the library of all structural models. Similarly, many threading approaches with the quadratic pairwise objective function use the optimal raw score as the primary measure of structure and sequence compatibility and estimate the statistical significance of the score assuming a normal distribution of the sequence scores threaded to a library of available models.

In the approach implemented by GenThreader (Jones, 1999), the neural network score determines the compatibility of the structure with the model. The input to the neural network is a set of values of different scores: sequence similarity scores, the solvent accessibility score, and the pairwise interaction scores. The Gibbs-sampling threading approach (Bryant, 1996) estimates the significance of the optimal score by comparison to the distribution of scores generated by threading a shuffled query sequence to the same structural model. The distribution of shuffled scores is assumed to be normal.

Lathrop *et al*. (1998) formulated a model-selection approach that does not rely on the optimal sequence-structure alignments. The compatibility of the sequence with a structural model is measured by the total alignment probability, where the probability is summed over all possible sequence-to-model alignments. This approach has been applied in the Bayesian fold recognition method (Bienkowska *et al*., 2000). The total probability is calculated using the filtering algorithm proposed and developed by White (1988). This method assumes that different structural folds (*see* Article 69, **Complexity in biological structures and systems**, Volume 7) are independent and equally probable structural hypotheses. The most probable model within the same fold category determines the prior probability of observing the sequence given the fold. The posterior probability of the fold given the sequence is calculated according to Bayes formula.

7. Performance of threading methods

The evaluation of different fold recognition (threading) methods takes place every two years during the Critical Assessment of Structure Prediction (CASP) (*see* Article 74, **Molecular simulations in structure prediction**, Volume 7) meeting. The prediction period is 3 months when different groups submit their predictions to a common depository. Targets for prediction are proteins that are about to have their structures solved. The CASP contest provides an opportunity to evaluate methods on the same sample set and in the context of truly "blind" predictions. This setting allows for performance comparison across methods using varied self-evaluation criteria applied by authors. Many threading approaches have been the subject of evaluation by past CASP contests. Examples of prediction methods that have been successful are: GenThreader (Jones, 1999), 3D_PSSM, (Kelley *et al*., 2000), FFAS (Rychlewski *et al*., 2000), SAM-2000 (Kelley *et al*., 2000), and PROSPECTOR (Skolnick and Kihara, 2001). Many other methods can be accessed at the CASP6 website **http://predictioncenter.llnl.gov/casp6/** (CASP, 2004) including 60 registered prediction servers. Over past CASP experiments, fold recognition methods have proved capable of recognizing distant sequence and structure similarities that are undetectable by sequence comparison methods. The evaluation of the last

CASP5 contest and description of several methods with best overall performance is described in Kinch *et al*. (2003).

Independently of the method, the accuracy of the prediction varies dramatically among proteins. Some proteins are much easier to predict than others and this can be recognized by consensus methods that automatically evaluate predictions generated by different algorithms. Consensus methods are generally more reliable than any single method alone. An example of a meta-server generating consensus predictions is Pcons **http://www.sbc.su.se/~arne/pcons/**. Figure 1 shows an example of a partially successful prediction for protein HI0817, *Haemophilus influenzae* (target T129 in CASP5 contest). The overall topology of three C-terminal helices of the structure is correctly recognized, while the rest of the molecule is mispredicted. Even with the correctly recognized topology, the alignment of the residues in those helices is shifted by four positions. Figure 2 shows an example of a successful prediction for the single-strand binding protein (SSB), *Mycobacterium tuberculosis* H37Rv, (target T151 in CASP5 contest). All secondary structure elements are correctly aligned as well as most loops. Exceptions are one internal loop that is missing a glycine residue and the C-terminal tail. The missing residue was absent from the original target sequence submitted for predictions. This last example demonstrates that threading can be very successful in predicting protein structure. However, much effort is still required from the research community to provide a true solution to the protein structure prediction.

Short Specialist Review

Acedb genome database

Richard Durbin and Edward Griffiths
Wellcome Trust Sanger Institute, Cambridge, UK

1. Introduction

Acedb (A C Elegans DataBase) was first developed by Jean Thierry-Mieg and Richard Durbin in the context of the *Caenorhabditis elegans* sequencing project in the early 1990s, with the aim of integrating the new sequence with existing genetic and physical map information, and research data from publications. In this era, prior to the World Wide Web, the software and data were made publicly available for researchers to download to provide a graphical interactive interface to the genome data.

It was adopted by many other genome projects and research communities, including those for the yeast, *Saccharomyces cerevisiae* (SGD), the fruit fly *Drosophila* (BDGP), and the model plant *Arabidopsis* (AAtDB) in addition to many smaller scale applications, and played a key role in the early stages of the human genome project in managing physical map construction and genome annotation. Many of these have now moved on to use dedicated relational database systems, but WormBase, the model organism database for *C. elegans*, and a large part of the curated sequence annotation for vertebrate genomes continue to use Acedb, as well as a continuing number of smaller groups.

With the adoption of server–client architectures and scripting languages such as Perl by the bioinformatics community in the 1990s, a server version of Acedb was provided and the AcePerl interface was developed by Lincoln Stein. These support World Wide Web displays and distributed use in larger scale environments. Since its inception, Acedb has been ported to DOS, Unix, MacOS, and Windows operating systems, and most related graphics environments. The scale of databases supported has increased from a few megabytes to tens of gigabytes, with Acedb able to manage annotation on the complete human genome.

2. Architecture

The data model underlying Acedb is neither a traditional relational database design, where data are stored in tables, nor a standard object-oriented design. One of the features that has facilitated the adoption of Acedb by biological researchers is that data are stored in objects that are relatively complex and can conform naturally to standard things that people name and refer to, such as clones, genes, alleles, and so on.

More formally, Acedb supports semistructured data arranged in hierarchical objects, in the same sort of way as ASN.1 (which underlies the NCBI's data design) or XML, which has become widely used since 2000 for data exchange (see Abiteboul *et al*., 2000 for a discussion of Acedb in the context of modern semistructured data theory). However, it is strongly typed, with the schema organized into a number of classes, with each class consisting of a hierarchical tree structure of user-definable tags and data fields. All permissible fields in the hierarchy for a class, known as *the model*, have strongly typed attributes, which can include references to objects in another specified class. Objects strictly contain only the tags and data necessary to represent the available data for that object. Objects, and indeed the schema, can be easily extended dynamically to add more detailed information in an object-specific fashion. Automatically maintained bidirectional references are also supported.

There have been a series of query languages developed, the first of which returned sets of objects satisfying a query, and the more recent AQL (Ace Query Language) giving tables specified using a more powerful declarative grammar. From the practical point of view, Acedb provides two-level caching with a shadow page system to support rollback and protection from hardware or software failure. It also manages indexes to speed up queries.

3. Design and use

The graphical interface to Acedb provides a multiple window hyperlink style environment, like modern Web browsers (see Figure 1). There are generic object displays that can show any object however specified. In addition, there are a number of powerful specific displays for genomic DNA sequence, genetic maps, microarray data, and so on, each of which has associated search and analysis tools. These include built-in interfaces to the gene-structure prediction program Genefinder (Phil Green), genetic map likelihood calculators, and sequence alignment and dot-plot viewers (Erik Sonnhammer). The specialized displays are highly configurable, relying on the values of certain object attributes for key information, but also able to read and display other attributes on the basis of configuration objects stored in the database.

Data can be entered, edited, and exported in a standard structured text file format (.ace files) on the basis of simple paragraphs per object with tag-value lines for attributes. This format is extremely compact as only the data and its associated tag need be specified; intermediate tags can be intuited from the class model. However, there are also interactive editing interfaces, both in the generic object display, and more powerfully in the specialized displays. One of the key continuing uses of Acedb is to support curation of gene exon–intron structures in genomic DNA. All edits are tagged with the time and user, so that a record of data origin is automatically maintained. Similarly, specialized output formats are available for relevant data types, including FASTA and EMBL/Genbank format for sequence, and GFF format for sequence features.

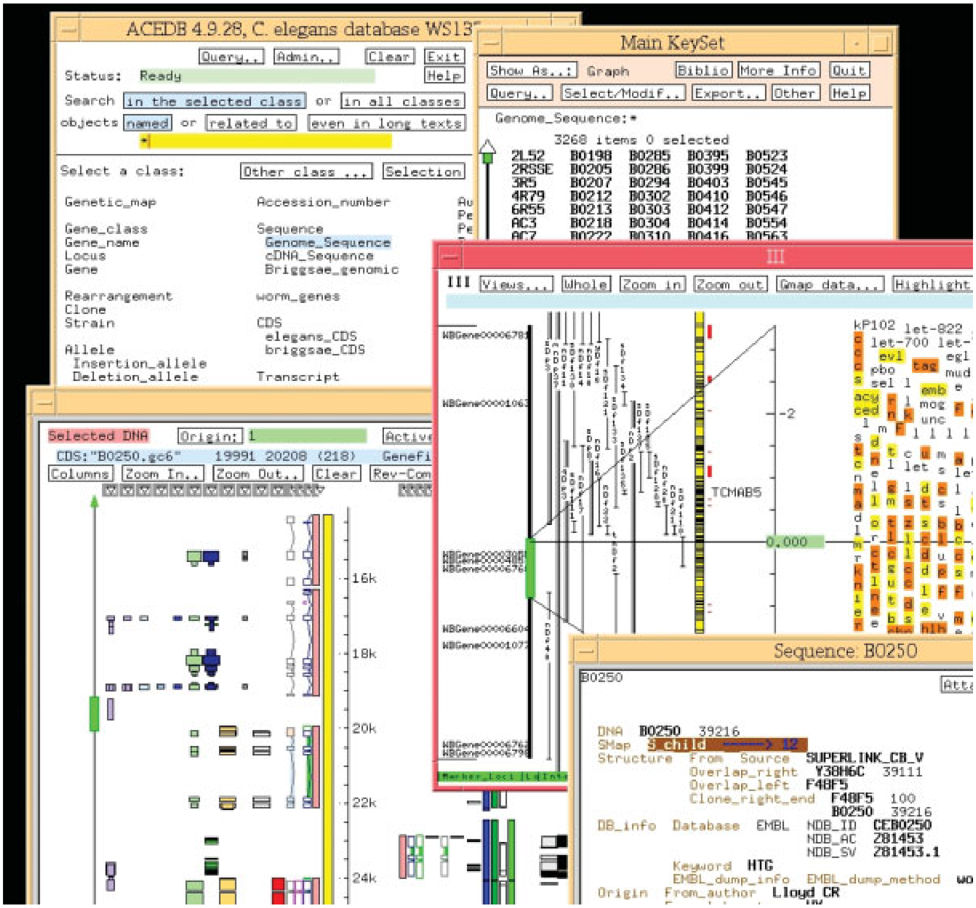

Figure 1 A view of the graphical interface to Acedb, showing examples of specific interfaces that are available, including a control window (top left) with examples of classes, a listing of objects in a class, a genomic DNA display showing genes and related evidence and features, a genetic map display with chromosomal rearrangements and gene locations, and a generic object display

4. Conclusions

Genome projects generate data as their primary output. These data are most valuable in the context of other biological information. Acedb developed within this environment to meet these needs. From the start, it was apparent that it would have to support a very wide range of depth of information, where a lot of detail is available about a few items, whereas very little if anything is known about most objects. Such is the nature of science. In addition, new types of information are always becoming available, so the design itself had to be flexible. And finally there needed to be an easy and intuitive way for researchers to find and interact with specific data.

Out of these requirements arose a novel general database management system and a complex domain-specific user interface for genome data annotation, both substantial software goals. In time, other solutions have been provided for most of the problems that Acedb addressed, many of them influenced to some degree by Acedb. However, Acedb performance and features remain competitive with these newer systems in the areas in which it is actively used and supported, and it is likely to continue to be used for the foreseeable future.

Acedb is freely available for download under the Gnu Public Licence (GPL) from the website **www.acedb.org**, which also contains much additional information.

Short Specialist Review

Design of KEGG and GO

Minoru Kanehisa
Kyoto University, Kyoto, Japan

1. Introduction

An early attempt to classify gene products into categories of cellular functions was done by Monica Riley for *Escherichia coli* (Riley, 1993). Her classification was largely biased toward metabolism, what was already known at that time, but the basic idea was adopted and extended by a number of groups doing complete sequencing of prokaryotic genomes, a notable example being the role category in the TIGR's Comprehensive Microbial Resource (Peterson *et al*., 2001). Obviously, such a classification system is useful for quickly uncovering metabolic and other capabilities of an organism by checking whether necessary components are present in the genome. GO (Gene Ontology) is a far more elaborate system, but its activities started from similar efforts for eukaryotic genome sequencing and annotation (*see* Article 82, **The Gene Ontology project**, Volume 8).

Another important classification scheme for protein functions is the EC (Enzyme Commission) numbering system for enzymes assigned by the Nomenclature Committee of the IUBMB and IUPAC (Barrett *et al*., 1992). The EC number represents a hierarchical classification of enzymatic reactions, six classes, subclasses and sub-subclasses, as well as serial numbering for substrate specificity. The EC numbers are used both as identifiers of reactions and as identifiers of enzymes that catalyze reactions. This duality makes it possible to superimpose the genomic content of enzyme genes (EC numbers) onto known metabolic pathways represented as networks of reactions (also EC numbers), thus to infer metabolic capabilities from the genome (Kanehisa, 1997). This feature was first successfully implemented in KEGG (Kyoto Encyclopedia of Genes and Genomes), providing more detailed pictures than the role category approach. For the purpose of common identifiers, the EC numbers were subsequently replaced by the KO (KEGG Orthology) identifiers in KEGG in order to extend to signaling and other types of regulatory pathways.

2. Design of GO

GO (**http://www.geneontology.org/**) is a database consisting of three structured, controlled vocabularies (ontologies) for describing how gene products behave in a cellular context (Ashburner *et al*., 2000). Its main objective is to compile and

share expanding knowledge about genes and gene products in different organisms. Despite its naming, GO lacks the basic properties for ontology in information science (Smith *et al*., 2003), but it has become a widely accepted standard for genome annotation in biological communities. The three ontologies are named molecular function, biological process, and cellular component, representing respectively molecular level functions of individual gene products, higher-level functions in the interaction network with other molecules, and locations within various structural components of the cell.

The three ontologies are separately defined structures of controlled vocabularies. More precisely, each structure is represented by the directed acyclic graph (DAG), which is somewhat different from the hierarchy, allowing a child to have multiple parents. Although no relations are defined across the three ontologies, intrinsic relations become apparent when GO terms are assigned to individual gene products. For example, dapB gene in *E. coli* codes for an enzyme, dihydrodipicolinate reductase (EC 1.3.1.26), which appears in the lysine biosynthesis pathway in bacteria. Thus, the gene product DapB would be associated with the GO terms:

GO:0008839: dihydrodipicolinate reductase activity
in the molecular_function ontology and
GO:0009089: lysine biosynthesis via diaminopimelate

in the biological_process ontology. They are part of separate DAGs, which include the EC number hierarchy for GO:0008839 and the generic to more specific descriptions of the biosynthesis pathways for GO:0009089. The cellular_component ontology contains terms for the anatomical structure of the cell, as well as for complexes of gene products, which are more often utilized in eukaryotes.

3. Design of KEGG

One of the most basic concepts in the design of KEGG (**http://www.genome.jp/kegg/**) is the level of abstraction illustrated in Figure 1. It also relates to the concept of nested graph. A graph is a set of nodes and edges, and a nested graph is a graph whose nodes can themselves be graphs. For example, the bottom item in Figure 1 is the three-dimensional (3D) structure of *E. coli* dihydrodipicolinate reductase (DapB), which is a graph with atoms as its nodes and atomic bonds as its edges. When the subgraph corresponding to each amino acid is converted to one of the 20 letters, such as C for cystein, a nested graph is obtained, emphasizing the information at the amino acid sequence level. In order to capture higher features at the protein network level, the whole graph object of the amino acid sequence or the 3D structure is better converted to a symbol, like DapB. Here, a higher-level graph represents the lysine biosynthesis pathway in *E. coli*, in which nodes are enzymes and edges are relations between enzymes.

Furthermore, in order to understand generic pathways (called reference pathways in KEGG) that are conserved among organisms, a huge graph object called the *gene universe* is considered in which nodes are genes (or gene products) and edges are, among others, ortholog (or sequence similarity) relations. The ortholog cluster of

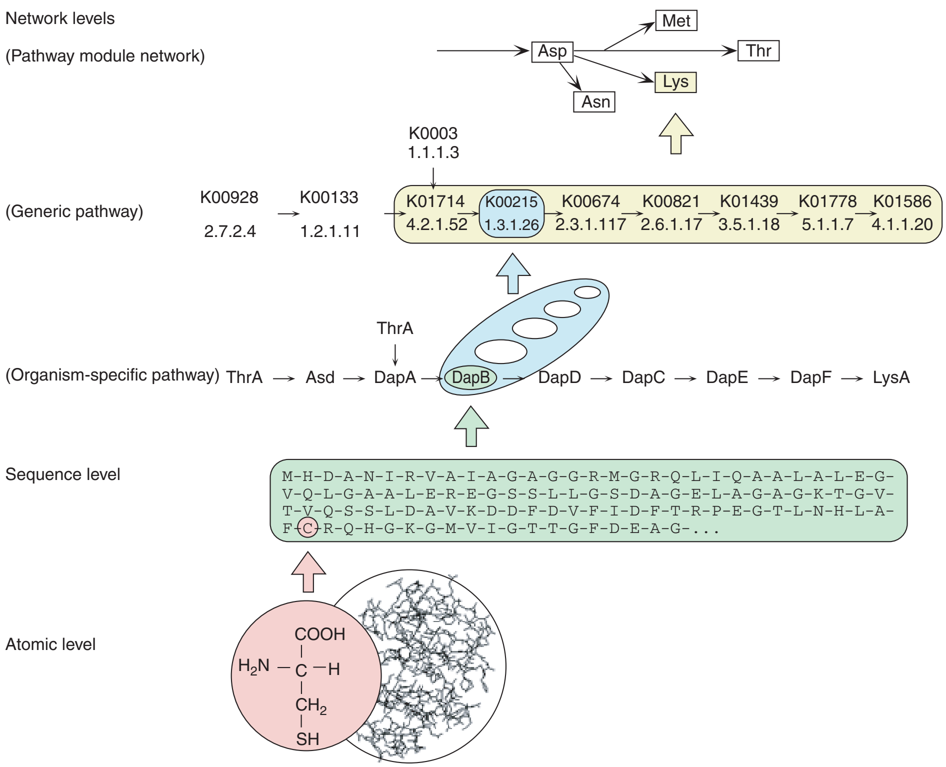

Figure 1 The level of abstraction represented by nested graphs

DapB proteins from various organisms would be a clique-like subgraph and it is converted to a node, with the KO (KEGG Orthology) identifier K00215. There may still be other types of modularity and hierarchy in still higher-level networks. For example, a lysine pathway module may be defined for the KO nodes K01714 to K01586 because of the continuous reaction steps and the coexpression (operon-like structure) information.

Thus, the *E. coli* gene dapB (accession number eco:b0031) is placed in the KEGG hierarchy as follows.

01100 Metabolism
  01150 Amino acid metabolism

        eco:b0031 dapB; dihydrodipicolinate reductase

Here, the third level corresponds to a KEGG pathway map (Lysine biosynthesis can be seen at **http://www.genome.jp/dbget-bin/get_pathway?org_name=ot&mapno=00300**). When compared to GO, this hierarchy is much simpler, but it roughly corresponds to the biological_process ontology and also includes some aspects (molecular complexes) of the cellular_component ontology. The information about the molecular_function ontology is organized in KEGG as many different

structural/functional hierarchies of proteins, including enzyme nomenclature (EC numbers) and subfamily classifications of G-protein-coupled receptors, ion-channel receptors, and other protein families. Each member of these groups or families is assigned a KO identifier, so the additional hierarchies are orthogonal to the fourth level in the hierarchy shown above, not the fifth level (individual genes) as in GO.

In contrast to GO where various types of functions are specified by controlled vocabulary, the specification of functions in natural language is deliberately left out in KEGG. Instead, functions are considered to be encoded, thus implicitly defined, in structural patterns of graph objects. In a similar way that sequence motifs and 3D structural motifs are identified, specific connection patterns of specific gene products may be related to specific cellular functions, such as lysine biosynthesis. In essence, the structural hierarchy of nested graphs also represents the functional hierarchy, enabling logical reasoning of higher-level functions from molecular level information.

4. Integration of genomics and chemistry

Both KEGG and GO can be used to analyze not only the information in the genome for understanding potential capabilities but also the information in the transcriptome or the proteome for understanding actual capabilities. For example, gene expression profiles in microarray experiments can be mapped to KEGG pathways or GO terms to uncover dynamic changes of cellular processes. KEGG can further be used to analyze the metabolome and the glycome, which represent cellular repertoires of small chemical compounds and glycans respectively. Such chemical substances are highly correlated with genomic contents, because they are encoded in the genome in terms of the biosynthetic and biodegradation pathways. In other words, knowledge about chemistry in the cell would greatly facilitate the process of deciphering the genome.

In KEGG, the integration of genomics and chemistry is based on the concept of line graphs (also called interchange graphs), in which nodes and edges are interchanged. The metabolic pathway is a network of chemical compounds in biochemistry textbooks, representing their conversions by enzymatic reactions. In contrast, the metabolic pathway is a network of enzymes (reactions) in KEGG, which can be linked to enzyme genes in the genome. These two networks are complementary; one can be related to the other by a line graph transformation, interchanging nodes and edges between compounds and enzymes. This means, for example, that if we know a set of chemical structures of secondary metabolites, we can infer reaction networks and then uncover a set of enzyme genes in the genome. More generally, the line graph analysis would uncover principles of how chemical or environmental perturbations cause genomic changes and vice versa. As more and more genomes are sequenced, we are beginning to understand the universality and diversity of the genomic space. However, we still have little knowledge about the universality and diversity of the chemical space that is relevant to life. KEGG is designed to explore both the genomic space and the chemical space by integrating genomes, networks, and chemistry in the three main databases named GENES, PATHWAY, and LIGAND.

Short Specialist Review

Simulation of biochemical networks

Andrzej M. Kierzek
Institute of Biochemistry and Biophysics, Warsaw, Poland

1. Introduction

Recent advances in experimental techniques of molecular biology have resulted in the unprecedented ability to measure and alter the properties of basic molecular components of complex biochemical processes occurring within the living cell. This has resulted in the creation of Systems Biology (Kitano, 2002), an emerging field aimed toward understanding systemic properties of living systems in terms of the knowledge of molecular components. One of the major scientific activities within this field is the mathematical modeling of cellular processes. Models of cellular processes most commonly take the shape of the networks of molecular interactions. Frequently, the complexity of biochemical systems makes impossible any analytical solution of the mathematical equations representing these models, thus creating the need to perform computer simulations. This chapter focuses on the computational approaches used in the simulation of biochemical network dynamics.

2. System representation

A biochemical reaction network may be described as a set of coupled chemical reactions. In this representation, the system is modeled as a set of N molecular species $(S_1, \ldots, S_N)$ interacting via M chemical reaction channels $(R_1, \ldots, R_M)$ in the reaction environment with volume V. The state of the system at time t is defined by the vector $\mathbf{X}(t) = (X_1(t), \ldots, X_N(t))$, where $X_i(t)$ is the number of molecules of substance S_i present in reaction environment. Amounts may be also expressed as concentrations, that is, ratios of the numbers of molecules to volume: $\mathbf{c}(t) = (c_1(t), \ldots, c_N(t))$, where $c_i(t) = X_i(t)/V$. Chemical reactions are described by the stoichiometric matrix $\mathbf{n}_{N,M}$, where $\mathbf{n}_{i,j}$ is the change of X_i resulting from one reaction R_j. A simple reaction network, representing the Michaelis–Menten mechanism of enzymatic reaction, is shown in Figure 1(a), as well as the corresponding stoichiometric matrix in Figure 1(b).

The notion of "reaction" is arbitrary in the modeling of biochemical networks. Elementary reactions in biochemical networks usually represent effective processes

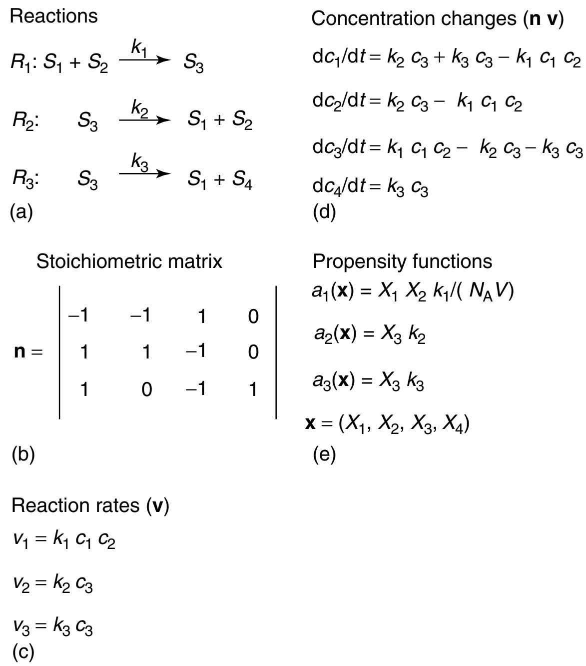

Figure 1 Example of a simple biochemical reaction network representing Michaelis–Menten mechanism of enzymatic reaction. (a) A set of three coupled chemical reactions. S_1, S_2, S_3, S_4 represent enzyme, substrate, enzyme substrate complex, and product respectively. Rate constants of three reactions are denoted by k_1, k_2, and k_3. (b) Stoichiometric matrix of the example reaction network shown in (a). (c) Reaction rates. (d) A set of simultaneous differential equations used to simulate the time evolution of the example reaction network. Note that the vector of concentration changes ($\mathrm{d}c_1/\mathrm{d}t, \ldots, \mathrm{d}c_4/\mathrm{d}t$) is the product of the stoichiometric matrix and the vector of reaction rates. (d) Propensity functions for the example network. Second-order rate constant k_1 is multiplied by $1/N_A V$ (V: volume of the reaction environment, $\mathrm{N_A}$: Avogadro's number) to represent the number of reactive molecular collisions occurring in the reaction environment in the unit of time. First-order rate constants k_2, k_3 represent the number of molecular conversions per unit time in both deterministic and stochastic chemical kinetics

in which many molecular processes are "lumped" together. For example, it is common to model the complex mechanism of transcription initiation by a single reaction, with the effective rate constant representing transcription initiation frequency. The level of approximation and detail depends on the knowledge available for the particular system and the scientific questions or engineering problems to be addressed.

3. Numerical integration of differential equations

Once the system is specified, the time evolution of $\mathbf{X}(t)$ may be studied. Most commonly, it is done by numerical solution of simultaneous differential equations

expressing the rates of concentration change for every substance in the system:

$$\begin{aligned} \frac{\mathrm{d}c_1}{\mathrm{d}t} &= f_1(c_1, \ldots, c_N) \\ &\ldots \\ \frac{\mathrm{d}c_N}{\mathrm{d}_t} &= f_N(c_1, \ldots, c_N) \end{aligned} \tag{1}$$

The functions $f_1, \ldots, f_N$ describe the dependence of the rate of concentration change of a particular substance on the concentrations of other substances in the system and are determined by the stoichiometric matrix and mechanism of reactions $R_1, \ldots, R_M$. They also contain quantitative parameters, referred to as rate constants; these values must be known or estimated in order to obtain quantitative results. An example of a system of differential equations describing a simple reaction network is shown in Figure 1(d).

The time evolution of biochemical reaction networks modeled by the approach described above may be simulated using standard algorithms for the numerical solution of simultaneous differential equations (Figure 2). Therefore, popular software packages such as MATHEMATHICA and MATLAB are frequently used for the simulation. There are also software environments dedicated to the modeling of biochemical reaction networks that implement the numerical solution of differential equations (e.g., GEPASI (Mendes, 1993), E-cell (Tomita *et al*., 1999); see Table 1 for comprehensive list). Examples of applications of this methodology are too numerous to be listed here. They include modeling of metabolic pathways (Wang *et al*., 2001), cell cycle (Tyson *et al*., 2001), and signal transduction cascades (Bhalla and Iyengar, 1999). Such simulations are relatively cheap computationally. Simulations of metabolic networks performed on the whole-cell scale were done in real time on a standard PC computer (Tomita *et al*., 1999).

4. Rule-based approach

The major obstacle in computer simulations of biochemical systems is the lack of knowledge of precise parameters (rate constants) of the reactions. One of the solutions to this problem is to use qualitative rather than quantitative models of biochemical reaction networks. In the qualitative approach, frequently referred to as "logical formalism" (Mendoza *et al*., 1999) or "rule-based simulation", the amounts of substances are replaced by discrete states (most commonly binary states), which denote "activation" levels of the molecular components of the system. This methodology is most frequently applied to so-called genetic networks in which "substances" represent genes and "reactions" represent regulatory influences of the particular gene product on other genes in the system. The binary states of the molecular components represent two activation levels of the gene ("on", "off" or "active", "inactive"). The state of a particular gene in the network is determined by a boolean (i.e., logical) function, which depends on the states of other genes in the system and network connectivity. Logical functions correspond to the rate expressions in equation 1, where it may be argued that they represent the sign of the rate. Here,

(c) Computation and visualization of metabolic flux distribution with FluxAnalyzer. (d) STOCKS software: kinetic model building and individual time courses computed with Gillespie algorithm

a positive sign means activation, while a negative sign denotes repression. In spite of such drastic simplifications, discrete models have provided useful predictions in studies of gene networks *Drosophila* embryos (Sánchez and Thieffry, 2003).

5. Stationary state analysis

Another way of solving the problem of sparse information on quantitative parameters is to study the flux distribution in the system at stationary state. The system at stationary state satisfies the following condition:

$$\mathbf{nv} = 0 \tag{2}$$

where **n** is the stoichiometric matrix and **v** is the flux vector, that is, the vector of all reaction rates (Figure 1c) in the system. Equation 2 may be analyzed using methods of linear algebra to study alternative flux distributions available for the system (Schuster *et al*., 2000) or to find the flux distribution that optimizes certain criteria, for example, rate of cell growth (Edwards *et al*., 2001). These methods require only information on the stoichiometric matrix or limited information on some of the fluxes. They were used to find alternative metabolic pathways, to indicate missing annotations of enzymes in bacterial genomes, and to predict mutant phenotypes by using only partial experimental knowledge of certain metabolic fluxes to calculate the flux distribution in cellular metabolism. There was also an interesting attempt to combine stationary state analysis of metabolic pathways with the rule-based simulation of underlying gene regulatory network (Covert and Palsson, 2002).

6. Stochastic simulations

The simulation methods described above are deterministic in a sense that they do not take into account random fluctuations in the outcomes of elementary reactions in the system. They consider reactions as continuous fluxes of matter. This approach is valid if the numbers of molecules are "effectively infinite", as happens in the case of chemical processes occurring in bulk. However, biochemical processes occur in very small volumes (on the order of 10^{-15} L) and involve very small numbers of molecules. There are examples of gene regulatory mechanisms in which as

few as 10 molecules of transcription factor interact with a single "molecule" of gene regulatory region. In such systems, stochastic fluctuations in the outcomes of individual reactions, resulting from random motion of the molecules, become significant and the deterministic simulation approaches are not valid. Moreover, it has been shown, both by theoretical studies and experiments, that stochastic fluctuations in elementary reactions may alter the course of important cellular processes such as gene regulation and metabolism and lead to heterogeneity in populations of genetically identical cells (Puchalka and Kierzek, 2004; Kierzek *et al*., 2001; Rao *et al*., 2002).

To account for the role of random effects in the dynamics of biochemical reaction networks, the stochastic formulation of chemical kinetics and Monte Carlo computer simulation methods need to be employed. In the stochastic formulation of chemical kinetics, the amounts of substances are expressed as the numbers of molecules ($\mathbf{X}(t) = (X_1(t), \ldots, X_N(t))$) rather than concentrations. Every reaction R_μ can be described by its propensity function a_μ such that:

$$a_\mu(\mathbf{x})\mathrm{d}t \equiv \text{probability, given the current state of the system } \mathbf{X}(t) = \mathbf{x}, \text{ that reaction } R_\mu \text{ will occur somewhere inside the volume } V \text{ in next infinitesimal time interval } (t, t + \mathrm{d}t). \tag{3}$$

Propensity functions for the simple example system are shown on Figure 1(e).

Stochastic kinetic simulation algorithms use the reaction probability density function $P(\tau, \mu|\mathbf{x}, t)$ (Gillespie, 1977) to generate a statistical sample of system time courses. By definition, $P(\tau, \mu|\mathbf{x}, t)\,\mathrm{d}\tau$ is the probability, given the state of the system $\mathbf{X}(t) = \mathbf{x}$, that the next reaction in the system will occur in the infinitesimal time interval $(t + \tau, t + \tau + \mathrm{d}\tau)$ and will be an R_μ reaction. The reaction probability density function has the form (Gillespie, 1977):

$$P(\tau, \mu|\mathbf{x}, t) = a_\mu(\mathbf{x}) \exp(-a_0(\mathbf{x})\tau), \text{ where } a_0(\mathbf{x}) = \Sigma_{1,\ldots M}^{a_\mu(\mathbf{x})} \tag{4}$$

In stochastic simulations, a random pair (τ, μ) is generated according to the joint probability density function $P(\tau, \mu|\mathbf{x}, t)$, and simulation variables are updated in the following way: (1) the state of the system is updated by adding the row of stoichiometric matrix describing reaction R_μ; (2) the time of the simulation t is increased by τ; and (3) the propensity functions of all the reactions are recomputed. Iteration of these steps, until the preset timescale is covered, results in a single time course of the system. An appropriate number of independent simulations generates a sample of time courses that are used to compute statistical properties of the system. This approach is frequently referred to as the exact stochastic simulation because it considers the individual reactive collisions occurring at exact time. No arbitrary time step is used and no assumptions other than the uniform distribution of molecules in the reaction environment are invoked. The most commonly used exact stochastic simulation algorithm is Gillespie's direct method (Gillespie, 1977; see Figure 3) that requires generation of two pseudorandom numbers in every iteration. Recently, Gibson and Bruck (2000) proposed the simulation algorithm that remains exact but requires only one call for random number generator per

Let the state of the system at the exact time t be:
$x(t) = (X_1, X_2, X_3, X_4)$

For reactions R_1, R_2,R_3 compute propensity functions a_1, a_2, a_3 (see Figure1). Compute the sum of propensity functions $a_0 = a_1 + a_2 + a_3$.

Generate two random numbers r_1,r_2 uniformly distributed over unit interval (0,1).

Generate the waiting time for the next reaction:
$\tau = (1/a_0)\ \ln(1/r_1)$

Choose next reaction μ such that
$a_1 + ,..., + a_{\mu-1} < r_2 a_0 \leq a_1 + ,..., + a_\mu$

Let us assume that reaction R_1 has been selected.

Update the system. Set simulation time to $t + \tau$ and change the numbers of molecules according to one elementary reaction R_1:
$x(t + \tau) = (X_1 - 1, X_2 - 1, X_3 + 1, X_4)$

Figure 3 Example of exact stochastic simulation. The figure shows a single iteration of Gillespie direct method (Gillespie, 1977) applied to the example network presented in Figure 1

iteration and updates the system in time proportional to the logarithm of the number of reactions, not to the number of reactions itself.

In spite of the availability of the efficient Gibson and Bruck algorithm, accuracy in exact stochastic simulation is achieved at the price of a significant computational burden since for every reactive collision happening in the system at least one random number must be generated. Owing to this fact, it is not practical to use exact stochastic simulation algorithms for biochemical networks involving intensive enzymatic reactions in which as many as 10^8 simulation events must be executed to simulate one second of the time course. Intensive reactions alone could be simulated, in the stochastic framework, by Gillespie's τ-leap method (Gillespie, 2001) in which the number of reactive collisions k_μ happening within the specified time step τ is computed for every reaction R_μ as $P(a_\mu \tau)$, a Poisson random variable with parameter $a_\mu \tau$. However, if the system contains even single reaction involving small numbers of molecules, accuracy of the τ-leap method requires a very small time step and performance of the simulation drops to the level of exact methods. Therefore, the major challenge in stochastic simulations of biochemical reaction networks is to design algorithms capable of efficient simulation of the systems including simultaneous reactions involving small numbers of molecules (e.g., gene expression) and intensive metabolic reactions.

The problem of efficient multiscale stochastic simulation has been addressed by the hybrid simulation algorithms that partition the system into "slow" and "fast" reaction subsets and subsequently apply exact stochastic simulation methods to "slow" reactions and the deterministic method or the τ-leap method to "fast" reactions (Haseltine and Rawlings, 2002; Puchalka and Kierzek, 2004). Recently,

Puchalka and Kierzek (2004) demonstrated that a novel hybrid simulation algorithm, dubbed "maximal time-step method", could be used to study stochastic effects in the biochemical reaction network involving gene expression, enzymatic activity, signal transduction, and transport processes simultaneously. The maximal time-step method is implemented in the recent version of STOCKS simulation software (Kierzek, 2002).

The simulation methods described above do not consider the spatial distribution of the molecules. The StochSim algorithm represents every molecule in the system as an individual software object that makes explicit treatment of positional information possible. In a single simulation time step, the program randomly selects two objects and executes one elementary reaction if the selected molecules can react and the unit-interval random number exceeds the reaction probability determined according to the rate constant. Unimolecular reactions are simulated by selecting a molecule and a pseudomolecule. StochSim has been applied to the simulation of signal transduction in bacterial chemotaxis. In recent simulations, the spatial clustering of the receptors in the cell membrane is explicitly simulated (Shimizu *et al*., 2003). Ability of incorporation of positional information comes at the price of computational cost; StochSim algorithm is slower than exact simulation algorithms of Gillespie and Gibson and Bruck.

Advances in Systems Biology motivate experimental work dedicated to in vivo determination of quantitative parameters that may be used to build quantitative models of cellular processes. As the knowledge of quantitative parameters of elementary interactions within the cell will accumulate, the methods described in this chapter are likely to gain importance and become standard tools of computational biology.

Short Specialist Review

Using the Python programming language for bioinformatics

Michel F. Sanner

The Scripps Research Institute, La Jolla, CA, USA

1. Introduction

The next generation of bioinformatics programs will have to (1) support the interoperation of rapidly evolving and sometimes brittle, computational software developed in a variety of scientific fields and programming languages; (2) support the integration of data across biological experiments and scales; (3) adapt to rapidly evolving hardware environments; and (4) empower users by allowing them to carry out operations unanticipated by the programmers such as trying new combinations of algorithms or new visualizations. These combined requirements of flexibility, portability, resilience to failure, programmability by the user, and responsiveness to changes in the models and the hardware pose a challenging software engineering problem. Below, we will briefly describe the key differences between compiled and interpretive languages, rapidly compare the Python programming language with other interpretive languages, and finally provide a couple of examples of large Python-based software development project in the field of bioinformatics.

2. Programming languages

In compiled languages (FORTRAN, C, C++, etc.), an executable has to be built (i.e., compiled and linked) from the source code before it can be executed. Extending or modifying these programs requires rebuilding the application after the source code has been modified. This cannot be done while the program is running. Moreover, these languages require complete and syntactically correct source code before compilation and testing become possible. Interpretive languages (Perl (Tisdall, 2003; *see also* Article 104, **Perl in bioinformatics**, Volume 8), Python (Lutz *et al.*, 1999), Tcl (Ousterhout, 1994), Ruby (Thomas, 2001), Scheme (Dybvig, 1996), Lisp (Steele, 1990), Basic (Lien, 1986), etc.) use a program called an *interpreter* to evaluate source code as it is read from a file or typed in interactively by a user. These languages are often referred to as *scripting* or *interpreted languages*. Applications written in these languages can be extended and modified while the program is running without having to quit, recompile, or restart the application.

Table 1 Simple classification of some programming languages

	Low-level ⟶ High-level
Compiled	FORTRAN, C, C++, Java
Interpretive	Unix-Shell, awk, Basic, Perl, Tcl, Scheme, Ruby, Python

Code can be executed and tested as it is written, even if only a small fraction of the complete application has been implemented, thus allowing the rapid exploration of novel hypothesis and the early determination of design flaws.

Programming languages can also be classified and described by placing them on a scale ranging from low- to high-level languages (Table 1). We will deem a language "high-level" if it provides: high-level data structures such as lists and associative arrays; mechanisms for preventing errors from aborting the application (exceptions); array boundary checking; and support for automatic memory management as part of the language. The more such features any particular language provides, the higher it will be ranked. Interpretive languages usually are higher level than compiled languages. Java is often mistaken for an interpreted language because the Java Virtual Machine interprets the Java bytecode. However, Java has no support for the dynamic evaluation of source code and hence it is more accurately considered a high-level compiled language.

3. Advantages of interpretive languages

Rapid development: The high-level and dynamic nature of interpretive language offers several advantages for scientific computing. The ability to quickly prototype software is particularly interesting in a research environment where the software requirements are constantly shifting as the understanding of the underlying science evolves.

Easy to learn: Their simple syntax and high-level data structures make it easier for nonprofessional programmers such as computational biologists to develop programming skills, enabling them to interact with data programmatically and eventually develop code on their own. For instance, Python is becoming an increasingly popular language for teaching computational skills (Schuerer *et al*., 2004).

Open-ended application extensibility: Software environments enabling end users to interact programmatically with their data and with the application using a simple yet fully fledged programming language provides the highest level of extensibility. While Graphical User Interfaces (GUIs) are an excellent way to abstract programming syntax and data structures, GUIs can only be implemented for anticipated ways of using a program. This lack of programmability associated with GUI-based interfaces greatly limits the application's range of capabilities and its extensibility. Modifying an application's source code enables unrestricted modifications; however, it is usually a difficult task and always presents the danger of corrupting the application. General-purpose scripting languages provide a safer and easier way to extend applications, while

providing the open-ended extensibility that is missing in GUI-based interfaces. In fact, scripting languages blur the line between users and developers.

Glue languages: Interpretive language can be used to integrate heterogeneous pieces of software written in a variety of compiled languages and let them interoperate.

Interpretive languages provide new solutions to the challenges mentioned in the introduction and are becoming increasingly popular for developing bioinformatics applications (BioPerl, 2005)(BioPerl), BioPython, 2005(BioPython), Chimera (Huang *et al*., 1996), PMV (Coon *et al*., 2001), Vision (Sanner *et al*., 2002), PyMol (Delano, 2002), WhatIf (Vriend, 1990), PHENIX (Adams *et al*., 2002), MMTK (Hinsen, 1997), VMD (Humphrey *et al*., 1996)), and for teaching programming concepts to biologists (Schuerer *et al*., 2004).

4. Performance

The main drawback of interpretive languages is that they are slower than compiled languages, typically by a factor of 15–40 (Cowell-Shah, 2004). When compiled languages appeared, they rapidly replaced assembly languages. The substantial increase in readability and portability they offered outweighed the associated potential decrease in runtime performance. Today, this pattern is repeating itself: the sustained increase of computational power in typical desktop computers makes interpretive languages a practical alternative to compiled languages for a variety of tasks. Moreover, we often have a wrong intuition about how much and where performance is needed. A key observation is that the bulk of the source code of programs used in computational biology deals with input and output, handling events, and bookkeeping of data structures. The computationally intensive parts are often confined to a few functions that amount to a small percentage of the total number of lines of source code, typically less than 10%. Hence, large amounts of code can be implemented in high-level interpretive languages without affecting the overall performance of the application.

5. Which scripting language is right for my application?

Scripting languages such as the various UNIX shell scripting languages and awk (Aho *et al*., 1988) have been available for a long time. However, these languages are arcane and limited in generality. They have been reserved to computer-savvy users. A number of high-level scripting languages are available today. Perl was one of the first to be widely used in scientific computing. It is a powerful language for writing highly concise scripts. However, the way its syntax and notation tends to promote obfuscation is not a desirable feature for reusing and sharing code. Perl is mainly used for writing relatively short, “use-once”-type scripts, but is ill suited for developing large and complex software applications (Raymond, 2001). It is also lacking a good interpreter shell for interactive code development. The Tcl

language is another example of a widely used scripting language. Unfortunately, its one strength – all data are represented as strings – is also its main weakness for scientific computing. This makes Tcl cumbersome and inefficient for numerical computations. The Tcl-shell is also relatively simple and underdeveloped.

Python appeared in 1991, and was designed from the outset as an object-oriented language while allowing for simple scripting. It supports multiple inheritance, introspection, self-documenting code, high-level data structures (i.e., lists and associative arrays called *dictionaries*), and exceptions and warning mechanisms. Its syntax was designed to be free of arcane symbols and to look like English text (i.e., pseudo-code). Python is open source and runs on virtually any computer from super computers to PDAs. New functionality can be added to the interpreter by loading extensions to the language at runtime. Such extensions can be organized into sets called *packages*. The standard Python distribution comes with a comprehensive library of extensions covering needs in areas as diverse as regular expression matching, GUI toolkits, databases, network protocols, numerical calculations, and XML processing to name a few. In addition, an active community of developers provides a variety of packages spanning all areas of computing, reflecting the diversity of Python's user community and application areas. Python extensions can be written both in the Python programming language and in compiled languages such as FORTRAN, C, or C++, thus allowing the incorporation of legacy code. Code written in compiled languages must be "wrapped" (i.e., turned into a Python extension) before it can be called from a Python interpreter. Semi-automatic tools (SWIG 2005) facilitate the process of wrapping compiled code. These extensions execute faster than those written using the Python language. However, they are platform-dependent (i.e., they need to be compiled for every hardware platform and operating system). With Python, it is possible to have "the best of both worlds" by implementing those functions that require the utmost in performance using a compiled language, while the remainder of the application can be written in a high-level and platform-independent language.

Python has been used as a "glue language" to integrate monolithic programs. With the wrapping mechanism described above, a scripting layer can be added to such programs, allowing them to interoperate within a Python interpreter (Delano, 2002); (Humphrey *et al*., 1996); (Huang *et al*., 1996). Using Python for scripting applications should be contrasted with using a custom scripting language (i.e., SVL (Santavy *et al*. 2005), BCL (Daelen 2005), SPL (Tripos 2005), batchmin (Schrodinger 2005), MATLAB (Hanselman *et al*., 2001), etc.). Custom languages often lack extensibility and tend to be domain specific since they are created by developers whose strengths are in a specific application domain. Because of their specificity, these languages will not benefit from the input of a large community. Designing a language is better left to people whose primary occupation is designing languages.

While an excellent scripting and glue language, Python is also a general-purpose, object-oriented programming language. It can be used as the primary language for the implementation of complete packages and applications that have the great advantage of platform independence (i.e., the same source code runs on all platforms). Unfortunately, the often wrong intuition about where and how much performance is needed tends to deter programmers from this approach. This

misconception about performance is difficult to overcome. However, designing and implementing components in the Python programming language first, provides several advantages: (1) The development cycle of a prototype is greatly accelerated through the use of a high-level language and the reuse of software components. It is not uncommon for a Python program to have 3–10 times fewer lines of source code than the same program written in C. (2) The design of software components can be validated rapidly. Python code can be tested as it is written. The ability to run code after only a fraction of an application or component has been implemented helps identify design problems early on. (3) Performance bottlenecks can be identified using Python's profiler and resolved by optimizing the Python code, or by implementing such parts in C or C++. Finally, (4) a potentially slow but working Python implementation is always available in the case that a C or C++ implementation cannot be loaded.

6. Examples of large python-based software developments

BioPython: (**http://biopython.org**) is an example of a joint international effort to create a modular and reusable set of tools in Python. Like its sibling projects, Bioperl, Biojava, and the other so-called Bio* (say: "bio-star") projects, it is developed under an open-source programming license. Contributions are made by dozens of people worldwide. Biopython "core" contributors regularly discuss and enforce a well-defined and consistent style to create a cohesive and integrated set of modules rather than a disjoint collection of programs. Modules are submitted concurrently with documentation and tests. In addition, on-line tutorials, "cookbooks", mailing lists, and bug-reporting software helps support the user community. Biopython provides support for parsing common bioinformatics file formats such as Fasta, GenBank, UniGene, SwissProt, FSSP, SCOP, and PDB; interfaces to common on-line destinations such NBCI and Expasy, and to locally run programs such as local NCBI BLAST, or ClustalW. It also provides pairwise and multiple alignment methods, a standard sequence class with methods such as "reverse complement" or "translate" for DNA, and "charge" and "pI" for proteins, and so on.

MglTools: (**http://www.scripps.edu/∼sanner/software**) is a collection of Python extensions developed in the author's laboratory, and dealing with various common tasks in structural biology, ranging from 3D visualization to the representation and manipulation of molecular data (Coon *et al*., 2001). Eleven packages comprising over 220 000 lines of code and over 1370 classes are implemented in the Python programming language. Ten additional packages wrap C and C++ libraries and provide an additional 200 classes. These components have been combined in various applications, including: PMV (Sanner, 1999), a general-purpose 3D molecule viewer (Figure 1a); ADT, a PMV-based graphical front end to the molecular docking program AutoDock (Morris *et al*., 1998); ARTK (Gillet *et al*., 2004a,b), an augmented reality program enabling the real-time blending of computer-generated graphics with live video of physical models of molecules; and Vision (Figure 1c) (Sanner

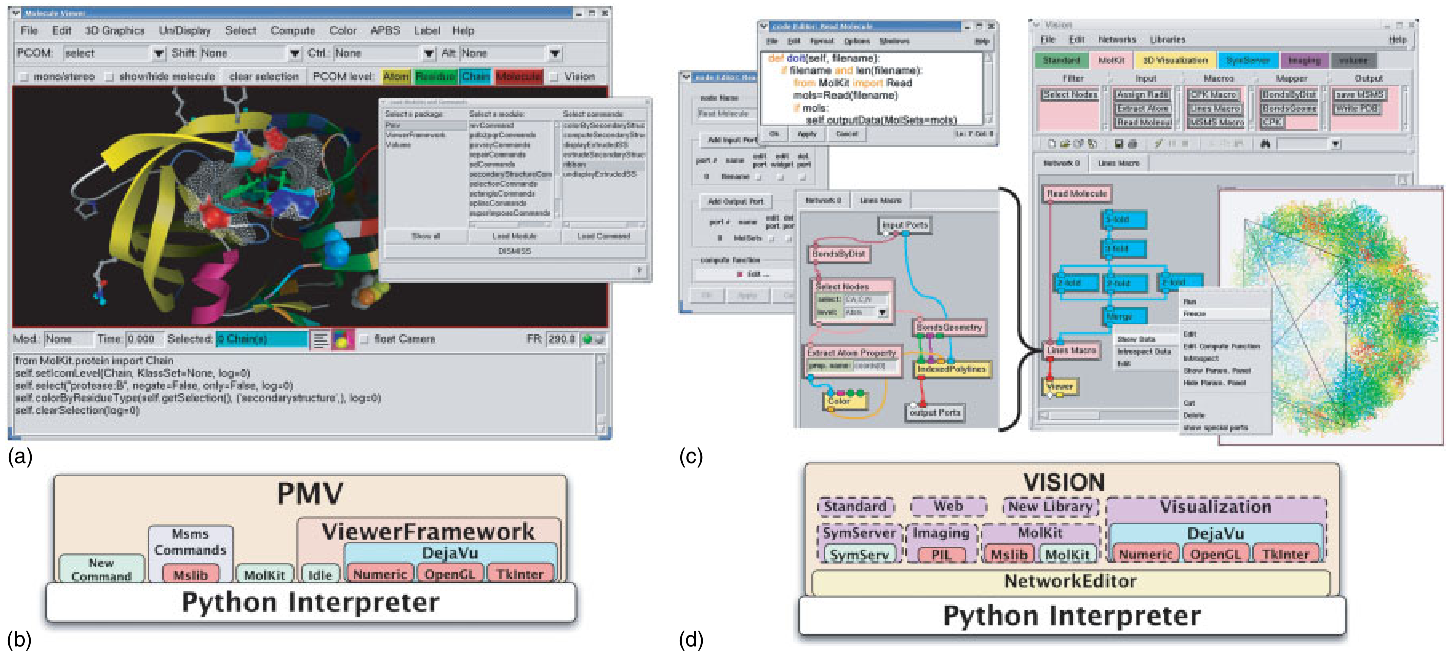

Figure 1 Two applications, PMV and Vision, built from, and sharing many software components. (a) PMV: a general purpose molecular visualization application. (b) Architectural layout of PMV. Nested boxes denote dependencies between Python packages. Packages with dark pink background are platform-dependent. (c) A molecular visualization application built using the Vision visual programming environment. A network used to display a viral capsid is shown. The subnetwork embedded in the “Lines Macro” is shown as an inset. The “node Editor” allowing inspecting and modifying nodes interactively has been started on the “Read Molecule” node. (d) Architectural layout of Vision. Libraries of Vision nodes are shown with dashed outlines. Note the number of software components shared with PMV

et al., 2002), a visual programming environment. PMV and ADT have been downloaded by over 9000 scientists (NCBR 2005).

These reusable software components and the applications built from them demonstrate the feasibility of the programming paradigm we have explored (Sanner, 1999) in which the Python interpreter is at the heart of all applications we create (see Figure 1b and d). In this approach, the software development strategy shifts from writing programs to developing software components. We found that Python's modular nature promotes the development of such components and we have experienced unprecedented levels of code reuse in the various applications mentioned above. Moreover, some of our software components have been reused by others. For instance, the ViewerFramework component underlying PMV has been reused in A. McCulloch's laboratory at UCSD to create a viewer for cardiac modeling and simulations. Similarly, Vision has been used and extended by various other laboratories for tasks as diverse as image analysis, astronomical calculations, and grid-based computing. These examples demonstrate the reusability of our software components beyond the boundaries of our laboratory, and scientific domain.

7. Conclusion

The concepts of modularity and compartmentalization of computational tasks are not new; however, time has shown that these concepts are poorly promoted by compiled languages. When programming in the latter languages, the goal is to write an application that produces the right result. There is little incentive to implement independent, and therefore reusable, software components for solving each particular subtask. In fact, even if the software is properly compartmentalized, special "main" functions have to be written to ascertain the independence and correctness of the various components. The intrinsic modular nature of Python, on the other hand, promotes the creation of self-contained components each implementing a specific functionality. These components can then be loaded into a Python interpreter, effectively extending the interpreter with new functionality. Moreover, this component naturally becomes available to any application running a Python interpreter.

As modern computational biology moves toward the study of larger systems, it will require the integration of computational methods and experimental data from a variety of scientific fields. Furthermore, the complexity of the models will require an unprecedented level of flexibility in the software tools to allow investigators to formulate and validate new hypotheses. The interactive and dynamic nature of interpretive languages, their relative simplicity, and their ease-of-use, make these languages excellent choices for creating software tools with these advanced and complex requirements. Therefore, these languages will play an increasingly significant role in the era of digital biology.

Acknowledgments

The development of the Python-based software components described in this article was supported through the NSF grant CA ACI9619020 and the NIH grant

RR08605. We would also like to thank Iddo Friedberg for helpful discussions. This is manuscript #17185-MB from the Scripps Research Institute.

Short Specialist Review

Perl in bioinformatics

R. Hannes Niedner and T. Murlidharan Nair
University of California, San Diego, CA, USA

Michael Gribskov
Purdue University, West Lafayette, IN, USA

1. Introduction

Advances in biology have generated an ocean of data that needs careful computational analysis to extract useful information. Bioinformatics uses computation and mathematics to interpret biological data, such as DNA sequence, protein sequence, or three-dimensional structures, and depends on the ability to integrate data of various types. The Perl language is well suited to this purpose.

An important practical skill in bioinformatics is the ability to quickly develop scripts (short programs) for scanning or transforming large amounts of data. Perl is an excellent language for scripting, because of its compact syntax, broad array of functions, and data orientation. The following are a few of the attributes of Perl that make it an attractive choice.

- Perl provides powerful ways to match and manipulate strings through the use of regular expressions. Changing file formats from one to another is a matter of contorting strings as required.
- Modularity that makes it easy to write programs as libraries (called modules).
- Perl system calls and pipes can be used to incorporate external programs.
- Dynamic loaders of Perl that help extend Perl with programs written in C as well as create compiled libraries that can be interpreted by the Perl interpreter.
- Perl is a good prototyping language and is easy to code. New algorithms can be easily tested in Perl before using a rigorous language.
- Perl is excellent for writing CGI scripts to interface with the Web.
- Perl provides support for object-oriented program development.

Projects such as the sequencing of the human genome produce vast amounts of textual data. In its early stages, the human genome project faced issues with data interchange between groups that were developing software, and Lincoln Stein has noted how Perl came to the rescue (Stein, 1996). Perl is certainly not the only

language that possesses these positive features – many of them are found, as well, in other scripting languages such as Python (*see* Article 103, **Using the Python programming language for bioinformatics**, Volume 8).

In the following section, we discuss some of the important Perl features that make it attractive to bioinformaticians. We refer in this article to Perl version 5.6–5.8, but encourage you to look into the exciting new features of Perl 6, which has been reengineered from the ground up (**http://dev.perl.org/perl6/**, 2005).

2. Why use Perl?

Looking at today's landscape of programming languages, one is offered a wide variety from which to choose. The difference between compiled and interpreted languages is explained sufficiently in other articles in this series (Sanner, 2004), thus it suffices here to say that compiled languages are usually selected for their superior performance, as reflected by the C/C++ implementation of computationally demanding algorithms such as BLAST, ClustalW, or HMMer, or for their specific capabilities such as comprehensive user interfaces or graphical libraries. Scripting languages (often used synonymously for interpreted languages) such as Perl, Python, PHP, Ruby, Tcl, and so on, on the other hand, are often favored for fast prototyping since the development cycle does not require code recompilation. With the ever-increasing computational power (Moore's Law) (Moore, 1965) available for bioinformatics tasks, performance issues lose their importance in contrast to ease of development and code maintainability. In the search for the right programming language, one might also encounter the distinction of object-oriented and procedural programming accompanied with evaluations of which languages to choose for each of these programming approaches. Again, detailed publications exist on this topic (Valdes, 1994; Kindler, 1988; **http://www.archwing.com/technet/technet_OO.html**, 2001; **http://search.cpan.org/~nwclark/perl-5.8.6/pod/perltoot.pod**, 2005); thus, we restrict ourselves to some brief explanations here.

Until recently, the most popular programming languages (e.g., FORTRAN, BASIC, and C) were procedural – that is, they focused on the ordered series of steps needed to produce a result. Object-oriented programming (OOP) differs by combining data and code into indivisible components, called objects, which are abstract representations of "real-life" items. These objects model all information and functionality as required by the application. OOP languages include features such as "class", "instance", "inheritance", and "polymorphism" that increase the power and flexibility of an object.

In bioinformatics, a DNA sequence might be represented as an object inheriting from a more general implementation that covers the properties of all biological sequences. OOP would code this object by describing its properties such as length, checksum, and certainly the string of letters that comprises the sequence itself. Then one would implement accessor methods to retrieve or set these properties, and also more complex functions such as transcribe() that would take as an argument an organism-specific codon matrix and transform the DNA object to an RNA object. In procedural (or sequential) programming, the code flow is driven by the "natural" sequence of events. OOP is generally regarded as

producing more reusable software libraries and better APIs (application programming interfaces) (**http://www.archwing.com/technet/technet_OO.html**; **http://search.cpan.org/~nwclark/perl-5.8.6/pod/perltoot.pod**, 2005).

While all these aspects certainly matter in one's choice of a language, our experience is that bioinformatics programming frequently is not done by computer scientists or trained programmers, but rather by researchers in bioscience who are trying to make sense out of their experiments. The priority is not the production of elegant and maintainable code but rather speed and ease of programming. As Larry Wall puts it, " ... you can get your job done with any 'complete' computer language, theoretically speaking. But we know from experience that computer languages differ not so much in what they make possible, but in what they make easy." In that regard, "Perl is designed to make the easy jobs easy, without making the hard jobs impossible" (Wall *et al*., 2000).

The high-level data structures built into Perl scale to any size and are merely restricted by the boundaries of the operating system and the amount of memory available on the host machine. Perl supports both procedural and object-oriented programming approaches and runs on virtually on all flavors of Unix and Linux. In addition, ActivePerl from ActiveState (**http://www.activestate.com/Products/ActivePerl/**, 2005) allows Perl to run even on Windows computers, and MacPerl (**http://dev.macperl.org/**, 2005) on Apple computers running System 9 and lower.

3. But Perl code is cryptic?!

At its simplest, Perl requires no declaration of variables. Variables belong to one of three classes: scalars (the scalar class supports strings, integers and floating point numbers), arrays, and associative arrays (arrays indexed by strings). Each type of variable is implicitly identified by beginning with a specific character: "$" for scalars, "@" for arrays, and "%" for associative arrays. Storage for variables is created when they are first referenced and released automatically when they pass out of scope. This automatic garbage collection is one of the high-level language features that makes Perl very convenient. Strings, integers, and floating point numbers are automatically identified and converted from one type to another as required. This is another powerful simplifying feature of Perl.

As with any high-level language, one can write very cryptic code in Perl – the distinction is that Perl has frequently been criticized for this. While the lack of a requirement for declaring variables exacerbates this problem and the automatic creation and initiation of variables can be a headache when typographical errors occur, these Perl-specific criticisms are, in our view, largely a red herring. Many style guides (e.g., perlstyle, (**http://search.cpan.org/~krishpl/pod2texi-0.1/perlstyle.pod**, 2005)) point out some common practices, not necessarily specific to Perl, that lead to "cryptic" code:

- usage of meaningless variable and function names (e.g., x1);
- removing extra (but structuring) white spaces and parentheses;
- writing more than one instruction (ended by a semicolon) on one line; or

- active attempts to obfuscate your code such as substitution of numeric values with the arithmetic expressions or usage of hexadecimal character codes for all characters in strings to name just a few.

Perl provides support for better programming style (for instance, the "strict" pragma that requires explicit declaration of variables) and for internal documentation (via the pod mechanism). Perl also supports high-level constructs such as subroutines (with support for both call-by-reference and call-by-value), libraries (called modules in Perl), and classes.

Perl is not strict about the completeness of the data. Missing or odd characters are not penalized. This can be thought as a downside of Perl, since Perl will perform operations on mixed types without complaining. This can come back to haunt you when spelling mistakes lead to logical errors, but can be easily circumvented by using the strict pragma and taking advantage of the many debugging features built into Perl, such as the using the -w switch to increase the verbosity of warnings and messages (**http://search.cpan.org/~nwclark/perl-5.8.6/pod/perlmodlib.pod#Pragmatic_Modules**, 2005; Gutschmidt, 2005).

4. Numerical calculations

With all the characteristics of a loosely typed language discussed so far, one might conclude that Perl cannot be used for numerical computations, but this is certainly not the case. Perl performs numerical calculations as double-precision floating point operations, and thus can be used for most computations that do not involve very high numerical precision. The Math::BigInt (**http://search.cpan.org/~tels/Math-BigInt-1.77/lib/Math/BigInt.pm**, 2005) and Math::BigFloat (**http://search.cpan.org/~tels/Math-BigInt-1.77/lib/Math/BigFloat.pm**, 2005) provide high-precision arithmetic for integers and floating-point numbers at the cost of somewhat slower execution in case you require more precision.

One can thus comfortably implement the classical algorithms such as learning by back-propagation of errors or Cleveland's locally weighted regression (LOWESS) in Perl. These are very frequently used algorithms in Bioinformatics for pattern recognition and microarray data normalization respectively. Having said this, however, Perl is nearly always a poor choice for large "number crunching". This is because Perl represents floating point numbers internally as strings and every numerical operation requires a conversion of string to floating point and back again. This can make Perl programs very slow if extensive calculations are required.

5. Regular expressions – Perl's most famous strong point

Pattern matching in text is simple and straightforward in Perl. Our experience is that code that can extend over a half a page in C or C++ can be easily written in one or two lines of Perl. Frequently, bioinformatics programs screen text documents for tokens that are identified by complex patterns. Regular expressions ("regex's" for short) are sets of symbols and syntactic elements used to match patterns of text.

They make it easy to represent complex patterns. For instance, searching for the pattern "ATT(C-or-G)(C-or-G)AAT" within 500 bases upstream of a promoter can be easily accomplished using this regular expression:

```
ATT[CG][CG]AAT.{0,500}TATAA
```

(the promoter is characterized by the Goldstein-Hogness or TATA box (Sudhof *et al*., 1987)).

Perl's built-in support for regular expressions is second to no other language, and there are three typical operations done with regular expressions:

```
Match:   m/PATTERN/;
Replace: s/PATTERN/REPLACEMENT/;
Split:   @tokenlist=split /PATTERN/, $string;
```

Additional facilities allow the pattern matching to be very flexible, for instance to be case-insensitive, to apply to every occurrence (global matching), or to translate sets of characters (useful for changing case or converting DNA Ts to RNA Us). It is simple to transform genetic sequences formatted with spaces and numbers into plain strings of letters as often required for further analyses:

$$\$\text{sequence} = \text{s/[\^{}ACGT]//g} \tag{1}$$

The above expression replaces every character that is NOT a capital A, C, G, or T with an empty string (well nothing), thus stripping all nonsequence characters (including carriage returns), lower case letters, and numbers from the sequence string. It is outside the scope of this article to provide a tutorial on regular expression, but several on-line and printed publications on this topic are available (Friedl, 2002; **http://www.regular-expressions.info/**, 2005).

Regular expressions also support bioinformatics resources such as, for example, Prosite (Sigrist *et al*., 2002) that provide access to organized collections of sequence motifs expressed as patterns.

6. File handling and databases

"Bioinformation", that is, data produced within the biosciences, is often produced as flat files (tag-field formatted text files). File formats developed by the Protein Data Bank (PDB) (Berman *et al*., 2002), Swissprot (Bairoch and Boeckmann, 1991), and Genbank (Benson *et al*., 2003) have become quasi-standards within the bioinformatics community. Perl makes it very easy to traverse large file systems, reading from and writing to files, and using its rich regular expression syntax to parse and transform textual file content. An example would be extracting the sequence string out of hundreds of individual files in Genbank format, while leaving out the information describing taxonomy, sequence features, bibliographic references, and other annotations. With these features, it is easy to understand why Perl naturally became the number one choice for the bioinformatics pioneers.

With the advent of relational databases, many bioinformatics repositories have been undergoing major reengineering efforts to reorganize their data storage technology from file repositories to relational databases. In addition, many labs and companies use relational database management systems (RDBMS) to store and organize annotation and experimental data. In Perl the Database Interface module (DBI) (**http://dbi.perl.org/**, 2005) provides a standardized and common interface for writing scripts that reference RDBMSs. Specific database drivers (DBDs) are called by DBI to communicate with particular RDBMS. The following code sample establishes a database connection ($dbh), which can be used to execute SQL commands:

```
use DBI;
my $dsn = 'DBI:mysql:my_database:localhost';
my $db_user_name = 'admin';
my $db_password = 'secret';
my $dbh = DBI->connect($dsn, $db_user_name,$db_password);
```

This modular architecture allows programmers to clearly separate common and RDBMS-specific code. While facilitating the production of database-independent code, DBI allows one to take full advantage of the features of a particular RDBMS via the specific functionality implemented in the DBD, or by handing off vendor-specific SQL statements directly to the RDBMS.

7. CPAN – the on-line Perl code library

Perl has been widely used not only by bioinformaticians but also by programmers in many other areas. Consequentially, there is an enormous wealth of Perl code available in the form of reusable software libraries, also called Perl modules (e.g., the DBI module mentioned above). The open repository for these Perl modules is the Comprehensive Perl Archive Network or CPAN for short. CPAN can be accessed not only at **http://www.cpan.org** (or many mirror sites) but also from within the standard Perl installation using the CPAN.pm module (**http://search.cpan.org/~andk/CPAN-1.76/lib/CPAN.pm**, 2005). When using Perl, you are part of a huge community – take advantage of it. Check CPAN first before you start implementing any major programming task since there is a very good chance that at least the core functionality is already available there.

8. Perl and the World Wide Web

Perl is widely used to develop web applications, and was adopted as the de facto language for creating content on the World Wide Web. Perl's powerful text manipulation facilities have made it an obvious choice for writing Common Gateway Interface (CGI) scripts. CGI is a standard for external gateway programs to interface with information servers such as http (or web) servers. An HTML document

that the web server retrieves is static, a CGI script, on the other hand, is executed in real time upon user request (via the web client) and helps to dynamically create a webpage. The standard Perl installation comes with the CGI module (CGI.pm), which can be used to streamline the creation of web pages. CGI.pm provides functionality to handle the GET and POST protocols, to receive and parse CGI-queries, to create Web fill-out forms on the fly, and to parse their contents and to generate HTML elements (e.g., lists and buttons) as a series of Perl functions, thus sparing you from the need to incorporate HTML syntax into your code (**http://stein.cshl.org/WWW/software/CGI/**, 2005).

The results of data analyses often require display in the form of charts and graphics. The GD module provides basic tools necessary for this. GD.pm is a Perl interface to Thomas Boutell's C-based gd graphics library that enables Perl programs to create color drawings using a large number of graphics primitives, and to format the images in PNG (**http://stein.cshl.org/WWW/software/GD/**, 2005) and other formats.

Perl also has a set of ready-to-use libraries to implement conventional http-based as well as the more recently developed RSS-, RPC-, and SOAP-based web services. This is important when one implements fully automated data retrieval from online services. For example, SOAP::Lite for Perl is a collection of Perl modules that provides a simple and lightweight interface to the Simple Object Access Protocol (SOAP) both on client and server side (**http://www.soaplite.com/**, 2005).

The LWP (Library of WWW access in Perl) modules provide the core of functionality for web programming in Perl. It contains the foundations for networking applications, protocol implementations, media type definitions, and debugging ability. Most notably, with LWP::UserAgent you can build "robots" to access remote websites as part of a program or even build your own robust web client (**http://search.cpan.org/~gaas/libwww-perl-5.803/lib/LWP.pm**, 2005).

9. XML processing

Perl's strong text parsing abilities make it no wonder that a host of modules have been developed to apply the power of Perl (and especially its regular expression syntax) to XML. The available modules cover the full range of XML standards, such as SAX and DOM, and are implemented either in Perl or provide a Perl interface to C-based libraries such as xerces, expat, or libxml/libxslt (**http://perl-xml.sourceforge.net/**, 2005).

10. BioPerl

BioPerl, the first in the series of Bio* projects, is an international association of developers of open source Perl tools for bioinformatics, genomics, and life science research formed in the early nineties and officially organized in 1995. BioPerl is a coordinated effort to convert and collect computational methods routinely used in bioinformatics and life science research into a set of standard CPAN-style, well-documented, and freely available Perl modules (**http://bioperl.org/**, 2005). BioPerl

provides you with a rather complete set of sequence analysis functions and more, thus the following is by no means a comprehensive listing:

- accessing the major biological databases for data retrieval;
- reading and converting all major sequence file formats;
- extracting sequence, parameters, and annotation from flat files (source data as well as program outputs);
- providing an interface to ClustalW, HMMer, BLAST, FastA, and other standard bioinformatics applications;
- parsing/representing protein structure (PDB) data;
- traversal of phylogenetic trees.

Usually, there is a steep learning curve before a novice programmer gets around to actually using BioPerl. This is because it is a complex collection of modules, it is not trivial to install, and requires an understanding of object-oriented programming. It is worth the effort required to work through the comprehensive documentation and examples provided on the World Wide Web since BioPerl can tremendously accelerate the development of complex and feature-rich applications after one masters the initial hurdles. In the event that you decide to go with your own implementation, keep in mind that you do not have to install BioPerl to use it – the BioPerl developers recommend "you just steal the routines in there if you find any of them useful" (**http://bio.cc/Bioperl/index_bioperl_original.html**, 2005).

11. Where to learn more

A tutorial on using Perl in Bioinformatics is presented in Article 112, **A brief Perl tutorial for bioinformatics**, Volume 8. Additional sources include:

Books:

- "Beginning Perl for Bioinformatics" by James Tisdall and published by O'Reilly and Associates Inc.
- "Sequence Analysis in a Nutshell" by Darryl León, Scott Markel and published by O'Reilly and Associates Inc.
- "Learning Perl" by Randal L. Schwartz, Tom Christiansen and published by O'Reilly and Associates Inc.
- "Programming Perl" by Larry Wall, Tom Christiansen and Randal L. Schwartz and published by O'Reilly and Associates Inc. (the Camel Book)
- "Perl Cookbook" by Tom Christiansen and Nathan Torkinton and published by O'Reilly and Associates Inc.
- "Mastering Algorithms with Perl" Jon Orwant, Jarkko Hietaniemi & John Macdonald and published by O'Reilly and Associates Inc.
- "Data Munging with Perl" by David Cross and published by Manning.
- "Object Oriented Perl" by Damian Conway and published by Manning.
- "Mastering Regular Expressions" by Jeffrey E. F. Friedl and published by O'Reilly and Associates Inc.

12. Conclusion

Bioinformatics is surging ahead at an increasing pace. The demand for the development of tools needed to analyze biological data is ever increasing. Developing scripts in Perl for prototyping, or suites of reusable Perl modules, allows one to contribute to a large research community developing and sharing Perl programs. As with any other programming language, fluency in the language comes with experience; clarity of the code largely depends on the programmer and his or her use of good programming practices. With the wealth of code already freely available, Perl is and will remain a language of significant impact in computational biology for many years to come.

Perl is a "feel-good" language that does not impose a particular style on you but rather serves your way of doing things. Perl therefore promotes the three virtues of a programmer as expressed in the editorial of the Camel book (Wall *et al*., 2000): Laziness, Impatience, and Hubris (as explained at **http://c2.com/cgi/wiki?LazinessImpatienceHubris**).

Short Specialist Review

The MATLAB bioinformatics toolbox

Robert Henson and Lucio Cetto
The MathWorks, Inc., Natick, MA, USA

1. MATLAB overview

MATLAB® (The MathWorks, Inc.) is a general-purpose technical computing language (*see* Article 103, **Using the Python programming language for bioinformatics**, Volume 8) and development environment that is widely used in scientific and engineering applications. MATLAB is used in many aspects of industrial and academic bioinformatics, including base calling algorithms for DNA sequencing, image analysis of microarrays, signal processing and classification of protein mass spectra, and pathway inference from gene expression results.

MATLAB includes many mathematical, statistical, and engineering functions as well as graphics and visualization tools. Toolboxes are collections of algorithms and functions that provide application-specific numerical, analysis, and graphical capabilities.

The Bioinformatics Toolbox provides access from within the MATLAB environment to genomic and proteomic data formats, analysis techniques, and specialized visualizations. It is designed for implementing genomic and proteomic sequence and microarray analysis techniques. Most functions in the toolbox are implemented in the open MATLAB language, enabling you to explore and customize the algorithms.

2. Bioinformatics toolbox features

Functions in the Bioinformatics Toolbox enable you to access many standard file formats for biological data, Web-based databases, and other on-line data sources. Supported file formats include FASTA, PDB, and SCF, and commonly used microarray data formats, such as Affymetrix®, GenePix®, and Imagene®. You can also directly interface with major Web-based databases, such as GenBank, EMBL, PIR, and PDB.

Once you have imported the sequences into the MATLAB environment, you can easily manipulate and analyze your sequences to gain a deeper understanding of your data. The toolbox provides routines for standard operations, such as converting DNA or RNA sequences to amino acid sequences using the genetic code.

You can report statistics about the sequences and search for specific patterns within a sequence. You can further manipulate your results by applying restriction enzymes and proteases to perform in silico digestion of sequences or create random sequences for test cases.

The toolbox also provides implementations in the MATLAB language of standard pairwise and multiple sequence alignment algorithms, including the Needleman–Wunsch (Needleman and Wunsch, 1970), Smith–Waterman (Smith and Waterman, 1981), and profile hidden Markov models (*see* Article 98, **Hidden Markov models and neural networks**, Volume 8) (Durbin *et al*., 1998). Once you have aligned your data, you can visualize your sequence alignments. You can also perform phylogenetic analysis and use the graphical user interface to explore phylogenetic trees. An example of using the toolbox for phylogenetic analysis is given below.

For work with amino acid sequences, the toolbox provides several protein-analysis methods, as well as routines to calculate properties of peptide sequences, such as isoelectric point and molecular weight. A graphical user interface lets you visually study protein properties such as hydrophobicity and create standard plots such as the Ramachandran plot of PDB data.

The Bioinformatics Toolbox also provides functions for filtering and normalizing microarray data, including lowess, global mean, and median absolute deviation (MAD) normalization. Specialized routines for visualizing microarray data include box plots, log–log, I-R plots, and spatial heat maps of the microarray. Using routines from the Statistics Toolbox, you can perform hierarchical and K-means clustering or use other statistical methods to classify your results (*see* Article 50, **Integrating statistical approaches in experimental design and data analysis**, Volume 7).

3. Phylogenetic analysis example

This example shows how the toolbox functions can be used to construct phylogenetic trees from Human Immunodeficiency Virus (HIV) and Simian Immunodeficiency Virus (SIV) sequence data.

Mutations accumulate in the genomes of pathogens, in this case the human/simian immunodeficiency virus, during the spread of an infection. This information can be used to study the history of transmission events and also as evidence for the origins of the different viral strains. There are two characterized strains of human AIDS viruses: type 1 (HIV-1) and type 2 (HIV-2). Both strains represent cross-species infections. The primate reservoir of HIV-2 has been clearly identified as the sooty mangabey (*Cercocebus atys*). The origin of HIV-1 is believed to be the common chimpanzee (*Pan troglodytes*) (Gao *et al*., 1999).

In this example, the variations in three coding regions from the complete genomes of 16 different isolated strains of the human and simian immunodeficiency viruses are used to construct a phylogenetic tree. These regions were chosen because they are relatively long and contain well-conserved domains (Alizon *et al*., 1986) (Rambaut *et al*., 2004). The sequences for these virus strains can be retrieved from GenBank, using their accession numbers. The three coding regions of interest, the

gag protein, the pol polyprotein, the least stable of the chosen regions, and the envelope polyprotein precursor, can then be extracted from the sequences.

In order to access the data from GenBank, we first create an array containing the information about the sequences. This includes a brief description, the accession number, and the indices of the coding sequences (CDS) in the genomes corresponding to the regions of interest. Lines starting with a % sign are comments in the MATLAB language.

```
%          Description                        Accession   CDS:gag/pol/env
data =  { 'HIV-1 (Zaire)'                    'K03454'     [1  2  8]    ;
          'HIV1-NDK (Zaire)'                 'M27323'     [1  2  8]    ;
          'HIV-2 (Senegal)'                  'M15390'     [1  2  8]    ;
          'HIV2-MCR35 (Portugal)'            'M31113'     [1  2  8]    ;
          'HIV-2UC1 (IvoryCoast)'            'L07625'     [1  2  8]    ;
          'SIVMM251 Macaque'                 'M19499'     [1  2  8]    ;
          'SIVAGM677A Green monkey'          'M58410'     [1  2  7]    ;
          'SIVlhoest L'Hoest monkeys'        'AF075269'   [1  2  7]    ;
          'SIVcpz Chimpanzees Cameroon'      'AF115393'   [1  2  8]    ;
          'SIVmnd5440 Mandrillus sphinx'     'AY159322'   [1  2  8]    ;
          'SIVAGM3 Green monkeys'            'M30931'     [1  2  7]    ;
          'SIVMM239 Simian macaque'          'M33262'     [1  2  8]    ;
          'CIVcpzUS Chimpanzee'              'AF103818'   [1  2  8]    ;
          'SIVmon Cercopithecus Monkeys'     'AY340701'   [1  2  8]    ;
          'SIVcpzTAN1 Chimpanzee'            'AF447763'   [1  2  8]    ;
          'SIVsmSL92b Sooty Mangabey'        'AF334679'   [1  2  8]    ;
          };
names = data(: , 1); acc = data(: , 2); cds = data(: , 3);
```

We can now retrieve the sequence information from the NCBI GenBank database, using the *getgenbank* function.

```
% Store the number of viruses
numViruses = size(data,1);
% Loop over each entry and download data from GenBank
for i = 1:numViruses
   seqs_hiv(i) = getgenbank(acc{i});
end
```

The next step is to extract the CDS for the GAG, POL, and ENV coding regions from the sequences. Then, extract the nucleotide sequences using the CDS pointers. The code below shows how to do this for the first sequence.

```
% Extract the sequence and CDS for the first sequence
theSequence = seqs_hiv(i).Sequence;
CDSs = seqs_hiv(i).CDS(cds{1},:);

% Extract the coding regions
gag{i} = theSequence(CDSs(1,1):CDSs(1,2));
pol{i} = theSequence(CDSs(2,1):CDSs(2,2));
env{i} = theSequence(CDSs(3,1):CDSs(3,2));
```

The Bioinformatics Toolbox can generate phylogenetic trees from either nucleotide or amino acid sequences. In this example, we will use the amino acid sequence of the coding regions to construct the trees. The translated sequence information is stored in the GenBank data structure, so we can extract the amino acid sequences from there or we can use the toolbox to calculate the sequences.

```
% Use nt2aa to convert nucleotide sequences to amino acid sequences
aagag{i} = nt2aa(gag{i});
aapol{i} = nt2aa(pol{i});
aaenv{i} = nt2aa(env{i});
```

To get some idea of how closely related the sequences are, we can use the global alignment functions from the toolbox to align some of the sequences.

```
% Align the two HIV-1 sequences using the default options
% score is in bits
hiv1_hiv1NDK_score = nwalign(aagag{1},aagag{2})
hiv1_hiv1NDK_score =
  1060.67
```

Figure 1 shows the global alignment of the two HIV-1 GAG proteins.

```
% Align the HIV-1 and HIV-2 sequences - score is in bits
hiv1_hiv2_score = nwalign(aagag{1},aagag{3})
hiv1_hiv2_score =
  570.00
```

Figure 2 shows the global alignment of the HIV-1 (Zaire) and HIV-2 Senegal GAG proteins.

The first two sequences are clearly very closely related. The HIV-1 and HIV-2 sequences have regions of similarity but also large regions that are significantly different.

In this example, we will use a distance-based method to generate the phylogenetic tree. There are two steps to creating distance-based phylogenetic trees (Page and Holmes, 1999). We first calculate all pairwise distances between the sequences and then construct the hierarchy from these distances. We can use many different metrics to measure the distance between two sequences, based on statistical and evolutionary models of how mutations occur. The Bioinformatics Toolbox provides many of the standard metrics including the Jukes–Cantor (Jukes and Cantor, 1969), Kimura (Kimura, 1980), and Tajima–Nei (Tajima and Nei, 1984) methods. You can also create a custom function to add your own metric to the toolbox. In this example, we will use the Jukes–Cantor distance, which assumes an equal rate of mutation for all nucleotides or amino acids. This approach clearly has some limitations and does not take into account the possibility of commonly occurring events in retroviruses such as crossover or recombination (Salemi *et al*., 2003).

```
gagd = seqpdist(aagag,'method','Jukes-Cantor');
```

Figure 1 Global pairwise alignment of GAG proteins from HIV-1 (Zaire) and HIV-1 NDK (Zaire)

This function creates a matrix of the pairwise distances between the 16 sequences. We can now use this information to build a hierarchical tree. There are several methods used for building trees from pairwise distances. The most commonly used is the Unweighted Pair Group Method with Arithmetic Mean (UPGMA) method. You can also choose from other linkage methods including single, complete, and weighted PGMA (Durbin *et al*., 1998).

```
gagtree = seqlinkage(gagd,'UPGMA',names)
```

Figure 2 Global pairwise alignment of GAG proteins from HIV-1 (Zaire) and HIV-2 (Senegal)

We can now plot the tree (Figure 3) and add a title.

```
plot(gagtree,'type','cladogram');
title('Immunodeficiency virus (GAG protein)')
```

If we repeat this process with the ENV (Figure 4) and POL (Figure 5) proteins, we see similar but not identical trees.

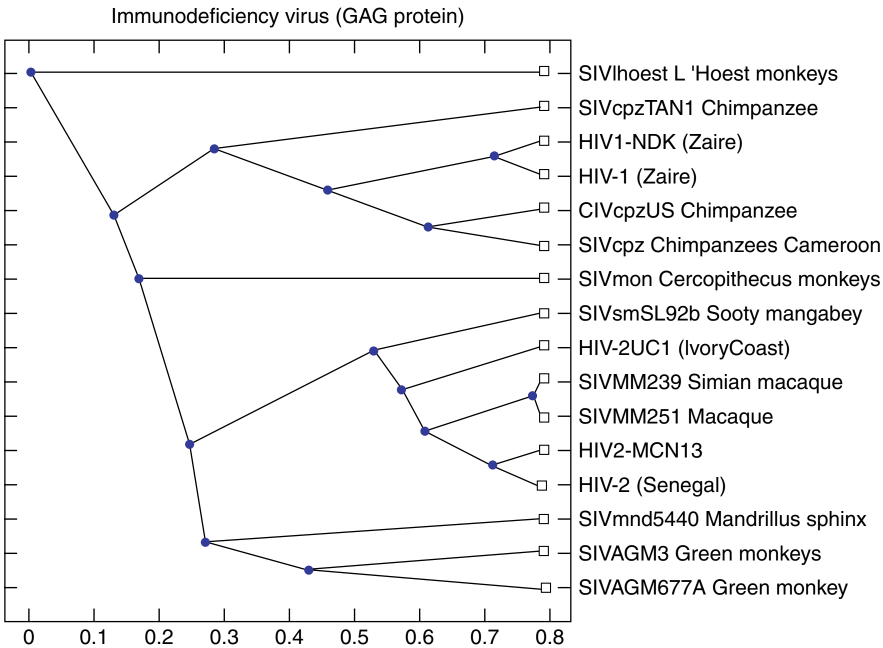

Figure 3 Phylogenetic Tree for GAG protein

The trees are slightly different, although they do show some clear trends. For example, the HIV-1 sequences always cluster together with the chimpanzee sequences and the HIV-2 sequences cluster with the SIV sequences from the sooty mangabey, as expected. One way to average out the three trees is to create a weighted consensus tree (Figure 6).

```
% calculate weights
weights = [sum(gagd) sum(pold) sum(envd)];
weights = weights / sum(weights);
% weighted average
dist = gagd .* weights(1) + pold .* weights(2) + envd .* weights(3);
% construct tree
tree_hiv = seqlinkage(dist,‘UPGMA’,names);
plot(tree_hiv,‘type’,‘cladogram’);
title(‘Immunodeficiency virus (Weighted Consensus Tree)’)
```

Using the same sequences to generate a maximum parsimony tree in PHYLIP (Felsenstein, 1989) produces a similar tree with the same distinct Chimpanzee/HIV-1 and Sooty mangabey/HIV-2 clusters.

4. Conclusion

Bioinformaticists have traditionally had to invest a great deal of time programming math and statistics algorithms in a short time frame. MATLAB and the Bio-

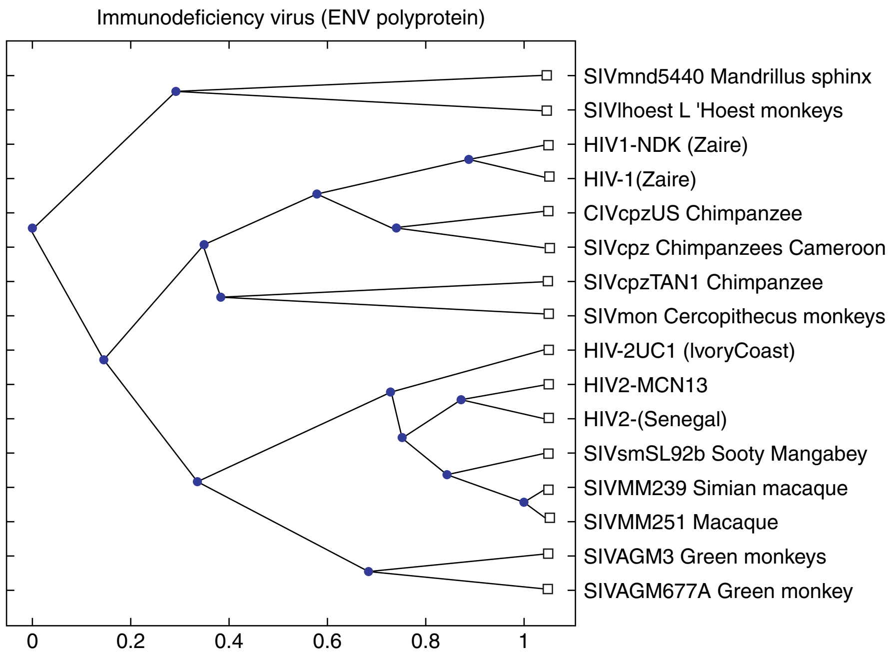

Figure 4 Phylogenetic Tree for ENV polyprotein

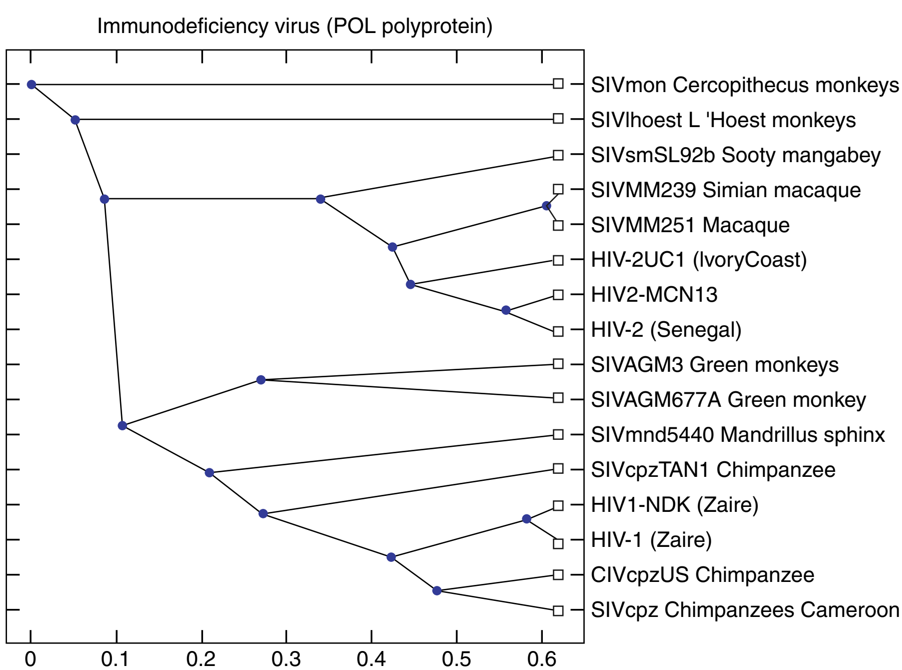

Figure 5 Phylogenetic Tree for POL polyprotein

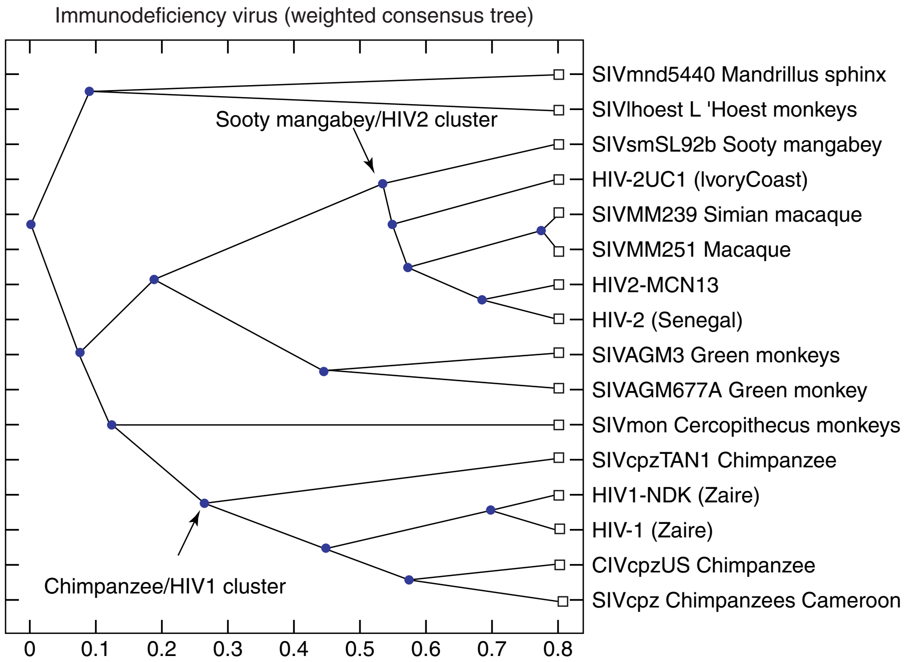

Figure 6 Weighted Consensus Phylogenetic Tree for HIV Polyproteins

informatics Toolbox provide bioinformaticists with a powerful development environment tool set for their mathematical and statistical work.

Short Specialist Review

Gibbs sampling and bioinformatics

Xiaole Shirley Liu

Dana-Farber Cancer Institute, Boston, MA, USA

1. Gibbs sampling introduction

Gibbs sampling is a variation of the Metropolis–Hastings algorithm, and one of the best-known Markov chain Monte Carlo methods. The algorithm was developed by Geman and Geman (1984), and named after the American physicist Josiah Willard Gibbs (1839–1903) in reference to the similarity between the sampling algorithm and statistical physics. It is useful when the joint or marginal distribution of two or more random variables is too complex to directly sample, but the conditional densities of each variable are available. Starting from initial values, a Gibbs sampler draws samples from the distribution of each variable in turn, conditional on the current values of the other variables. The sequence of the samples is a Markov chain. As the chain approaches infinity, the distribution of all variables approximates the joint distribution and the distribution of each variable converges to its marginal distribution (see Gelfand and Smith, 1990 and Casella and George, 1992 for details).

2. Gibbs sampling application to sequence motif finding

Gibbs sampling was first introduced to bioinformatics to detect local sequence patterns or motifs shared by multiple sequences (Lawrence *et al.*, 1993). These patterns often reflect similar biological functions, for example, motifs shared by promoters of multiple genes may indicate similar gene expression regulation. In the motif finding problem, there are two random variables involved: a position-specific weight matrix θ of width w to represent residue frequencies at each position of the motif; an alignment $A = (a_1, a_2, \ldots, a_n)$ to describe the location of the motif occurrence within each of the n sequences. Starting from random initial alignment, the Gibbs sampler iteratively updates the motif θ and the alignment A in turn conditional on the other variable. Liu (1994) observed that θ can be integrated out explicitly or "collapsed", and the alignment location of one sequence can be updated on the basis of the alignment of all other sequences. The collapsed Gibbs sampler picks a sequence i at random (or in a certain order), and estimates θ by counting the residues at each aligned position from all other sequences (plus some

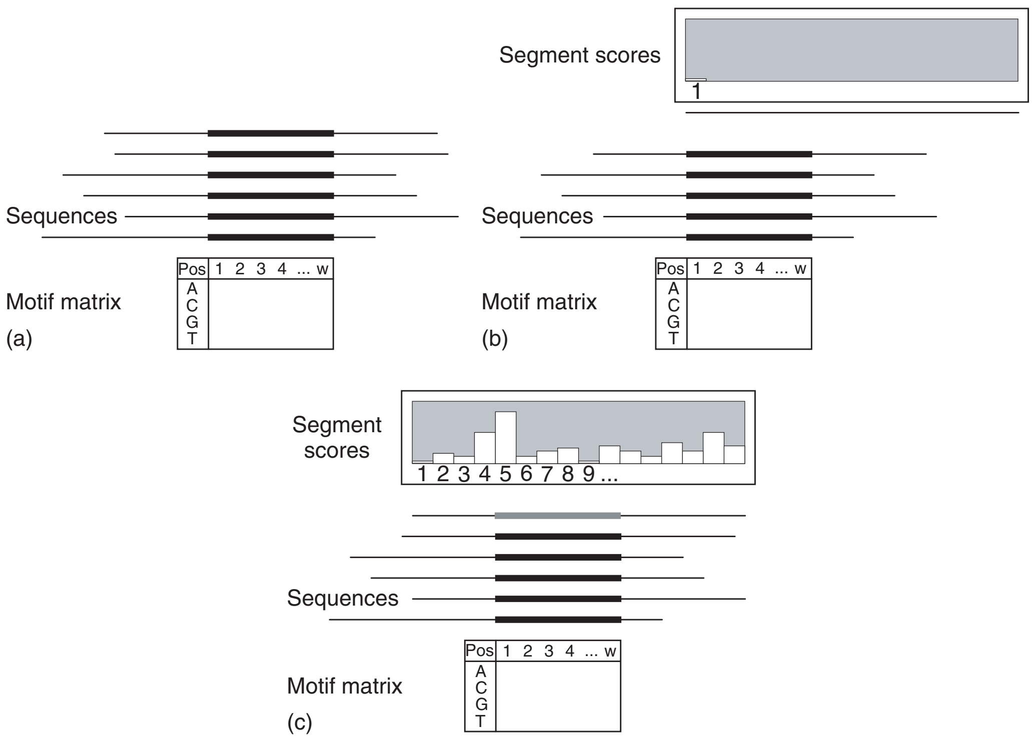

Figure 1 Gibbs sampling procedure for sequence motif finding. (a) One w-mer from each sequence is randomly picked to establish the initial motif probability matrix and initial alignment. (b) During Gibbs sampling iterations, a sequence i is picked at random and its contributing w-mer removed from the motif. The current motif is used to score every w-mer in sequence i. (c) A new w-mer in sequence i is sampled to add to the motif and put sequence i back to the alignment. The probability of picking a w-mer is proportional to its score. In Gibbs sampling, processes (b) and (c) are iterated until the motif converges

pseudocounts). Given this θ, each segment of width w in sequence i can be scored, and a new is sampled from this score distribution (Figure 1). The score is the probability of generating the segment by the motif over the probability of generating it by the general background, and thus preference is given to a segment that is similar to the motif yet different from the background.

Since the original Gibbs sampler was applied to the motif finding problem, there have been many improvements to make it more flexible in analyzing biological sequences. The Gibbs Motif Sampler (Liu *et al*., 1995) allows variable motif occurrences in each sequence by concatenating the sequences into one and checking each segment's sampled rate at stationary distribution. It also allows gaps in motifs by sampling only information-rich positions. AlignACE (Roth *et al*., 1998) finds multiple distinct motifs in the sequences by iteratively masking out reported motifs, and measures the goodness of a motif on the basis of whether the pattern is enriched compared to the whole-genome sequence. BioProspector (Liu *et al*., 2001) improves the motif specificity by introducing Markov dependency in the nonmotif background and can find two-blocked motifs with variable-sized gaps

in each sequence. Zhou and Liu (2004) improved the motif models by considering pairs of correlated motif positions. In higher eukaryotes, the sequences to be analyzed are much longer, and motifs (either the same or different motifs) often occur in close proximity to form modules. CompareProspector (Liu *et al*., 2004) reduces the search space by starting the search from subsequences conserved in evolution and sampling alignments weighted by evolutionary conservations. CisModule (Zhou and Wong, 2004) looks for modules where motif clusters reside. Given the module and motif locations, CisModule updates the motifs; given the motifs, CisModule first updates the module locations, and then samples the motif locations within each module.

3. Other Gibbs sampling applications

In the postgenomics era, high-throughput experiments are routine procedures in biomedical research. Gibbs sampling is well suited for conducting inference on these high-throughput data. We will discuss two of the most successful Gibbs sampling applications: haplotype inference and microarray bicluster analysis.

Single-nucleotide polymorphisms (SNPs) in the genome may help map complex disease genes and influence drug response. However, high-throughput SNP genotyping and analysis is inefficient and error prone. Usually, a set of closely linked loci has a limited collection of genotypes called haplotypes. Given a population of observed multilocus phenotypes, inferring each individual's haplotype is more informative and robust. The two variables involved here are the population haplotype frequencies θ and the assigned haplotype pairs $Z = ((z_{11}, z_{12}), \ldots, (z_{n1}, z_{n2}))$ that are compatible with the observed phenotypes. Gibbs sampler can converge on the stationary distribution of the two variables by iteratively updating the two variables in turn conditional on the other. Stephens *et al*. (2001) use the collapsed Gibbs sampler by iteratively picking an individual at random and updating his/her haplotype on the basis of the haplotype assignments of all other people. This method could be too computationally intensive when the number of SNPs in linked loci is too large. Niu *et al*. (2002) adopt the partition ligation strategy by dividing the long loci into small blocks, performing haplotype inference on each, and finally ligating the short haplotypes together.

Over the last 8 years, microarray experiments have become the standard procedure to profile the genome-level gene expressions. After microarray data are collected over a large number of biological samples or experimental conditions, clustering analysis can be conducted to find group of genes or conditions with similar expression profiles. When the number of samples or conditions is very large, often, only a subset of genes over a subset of conditions forms a tight enough cluster. Deciding the genes and conditions assigned to such a bicluster can be achieved by Gibbs sampling. Sheng *et al*. (2003) first discretize the expression values, randomly assign initial genes and conditions to a bicluster, then update genes and clusters in turn. With fixed conditions in the bicluster, every gene i is reassigned on the basis of whether its expression profile under the clustered conditions is similar to the expression profiles of other genes in the bicluster. With fixed genes in the bicluster, every condition j is reassigned on the basis of whether the expression profile of

clustered genes under condition j is similar to those under all other conditions in the bicluster. Wu *et al*. (2004) use a Gibbs sampler that aims to find a bicluster with the largest number of genes whose expression profiles pass a similarity threshold under at least a certain number of conditions. Each sampling iteration removes a condition i in the bicluster, scores each nonclustered condition by counting the number of genes with similar expression profiles if the condition is added to the bicluster, and samples a new condition to the bicluster on the basis of this score. Both methods identify one bicluster at a time, and multiple biclusters can be detected by iteratively masking out the expression values assigned to a converged bicluster.

Short Specialist Review

Applications of RNA minimum free energy computations

Peter Clote
Boston College, Chestnut Hill, MA, USA

1. Introduction

The article "RNA secondary structure prediction" (*see* Article 96, **RNA secondary structure prediction**, Volume 8) discussed dynamic programming methods to predict the minimum free energy (mfe) E_0 and minimum free energy secondary structure S_0 of a given RNA sequence, using the Turner energy model (Xia *et al*., 1999), with experimentally measured negative, stabilizing base stacking energies and positive, destabilizing loop energies (hairpin loop, interior loop, etc.). Here, we survey a few applications of this method to determine regulatory regions of RNA and more generally to determine noncoding RNA genes.

2. Methods

A general, often-used approach in genomic motif finding is to fix a window size n, and scan through a chromosome or genome, repeatedly moving the window forward one position. The window contents may then be scored using machine-learning algorithms, such as weight matrices (Gribskov *et al*., 1987; Bucher, 1990), hidden Markov models (Baldi *et al*., 1994; Eddy *et al*., 1995; *see also* Article 98, **Hidden Markov models and neural networks**, Volume 8), neural networks (Nielsen *et al*., 1997; *see also* Article 98, **Hidden Markov models and neural networks**, Volume 8), and support vector machines (Vert, 2002; *see also* Article 110, **Support vector machine software**, Volume 8). While accurate detection of protein coding genes can be achieved using hidden Markov models (Borodovsky and McIninch, 1993; Burge and Karlin, 1997), by exploiting the nucleotide bias present in a succession of codons, such signals are less apparent in noncoding RNA genes.

Noncoding RNA (ncRNA) (Eddy, 2001; Eddy, 2002) is transcribed from genomic DNA and plays a biologically important role, although it is not translated into protein. Examples include tRNA, rRNA, XIST (which in mammalian males suppresses expression of genes on the X chromosome) (Brown *et al*., 1992), metabolite-sensing mRNAs, called *riboswitches*, discovered to interact with small ligands and up- or downregulate certain genes (Barrick *et al*., 2004), tiny noncoding RNA

(tncRNA) (Ambros *et al*., 2003), and miRNA (microRNA). MicroRNAs are ~21 nucleotide (nt) sequences, which are processed from a stem-loop precursor by Dicer (Tuschl, 2003; Lim *et al*., 2003) – see Figure 1, which depicts the predicted secondary structure for *C. elegans* let-7 precursor RNA. MicroRNA is (approximately) the reverse complement of a portion of transcribed mRNA, and has been shown to prevent the translation of protein from mRNA – this is an example of posttranscriptional regulation.

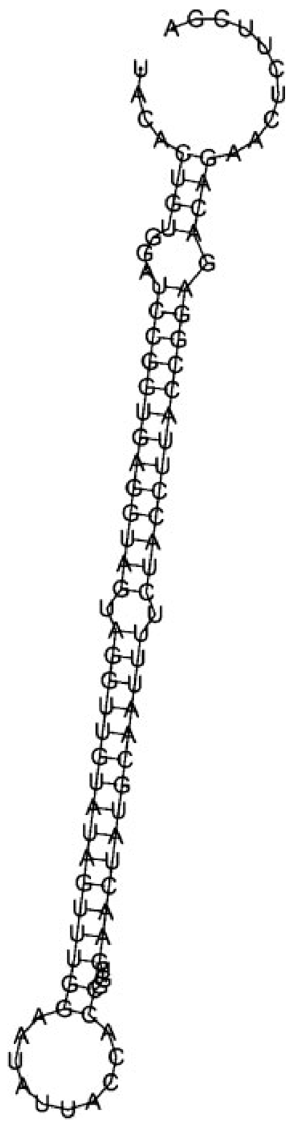

Figure 1 Predicted minimum free energy secondary structure of *C. elegans* let-7 precursor RNA; sequence taken from Rfam. Predicted minimum free energy for this 99-nt sequence is −42.90 kcal mol^{-1} (prediction made using `Vienna RNA package`)

For certain classes of ncRNA, there is a sufficiently well-defined sequence consensus or common secondary structure shared by experimentally determined examples, so that machine-learning methods such as *stochastic context-free grammars* (SCFG) have proven successful. RNA secondary structures can be depicted as a balanced parenthesis expression with dots, where balanced left and right parentheses correspond to base pairs and dots to unpaired bases.

In particular, by training an SCFG on many examples of tRNA, additionally using promoter detection with heuristics, T. Lowe and S. Eddy's program `tRNAscan-SE` identifies "99–100% of transfer RNA genes in DNA sequence while giving less than one false-positive per 15 gigabases" (Lowe and Eddy, 1997).

Exploiting the fact that ncRNA genes of the AT-rich thermophiles *Methanococcus jannaschii* and *Pyrococcus furiosus* have high $G + C$ content, Klein *et al*. (2002) describe a surprisingly simple yet accurate noncoding RNA gene finder for these and related bacteria. Lim *et al*. (2003) describe a novel computational procedure, `MiRscan`, to identify vertebrate microRNA genes. In a moving-window scan of the noncoding portion of the human genome, `MiRscan` uses `RNAfold` from the Vienna RNA Package (Hofacker *et al*., 1994) to search for stem-loop structures having at least 25 bp and predicted mfe of -25 kcal mol^{-1} or less. Subsequently, `MiRscan` passes a 21-nt window over each conserved stem-loop, then assigns a log-likelihood score to each window to determine how well its attributes resemble those of certain experimentally verified miRNAs of *Caenorhabditis elegans* and *Caenorhabditis briggsae* homologs.

Using the power of comparative genomics (alignments of homologous ncRNA genes from different organisms), Rivas and Eddy (2001) developed the program `QRNA` that trains a *pair stochastic context-free grammar*, given pairs of homologous ncRNA genes. Coventry *et al*. (2004) developed the algorithm `MSARI`, which assigns appropriate weights for local shifts of a ClustalW multiple sequence alignment of many (e.g., 11) homologous ncRNAs, in order to detect a conserved pattern of secondary structure. The authors suggest that a gene finder might then be trained on automatically generated multiple sequence alignments of RNAs, suitably corrected by their algorithm to identify the underlying sequence/structure alignment.

A related and equally important algorithmic task is the detection of regulatory and retranslation signals in the untranslated region (UTR), both upstream $5'$ and downstream $3'$ of the coding sequence (cds) of messenger RNA. For instance, Lescure *et al*. (1999) used Vienna RNA Package `RNAfold` in a simple screen to determine putative selenocysteine insertion sequence (SECIS) elements (see Hüttenhofer and Böck, 1998 for a review of selenocysteine incorporation); the authors subsequently performed (wet-bench) experiments to validate certain SECIS elements. Grate (1998) applied Eddy's RNA structure pattern searching algorithm program `RNABOB` in the search for SECIS elements in HIV. Bekaert *et al*. (2003) developed a model for -1 eukaryotic ribosomal frame-shifting sites, on the basis of a *slippery sequence* and a predicted *pseudo-knot* structure.

Recently, Washietl *et al*. (2005) described a noncoding RNA gene finder, based on a combination of mfe Z-score computations and comparative genomics. Here, the Z-score of the content of a current window of size n is defined by $\frac{x-\mu}{\sigma}$, where x is the mfe of the window contents, while μ, σ are respectively the mean and standard deviation of the mfe of random length n sequences having the same mono-

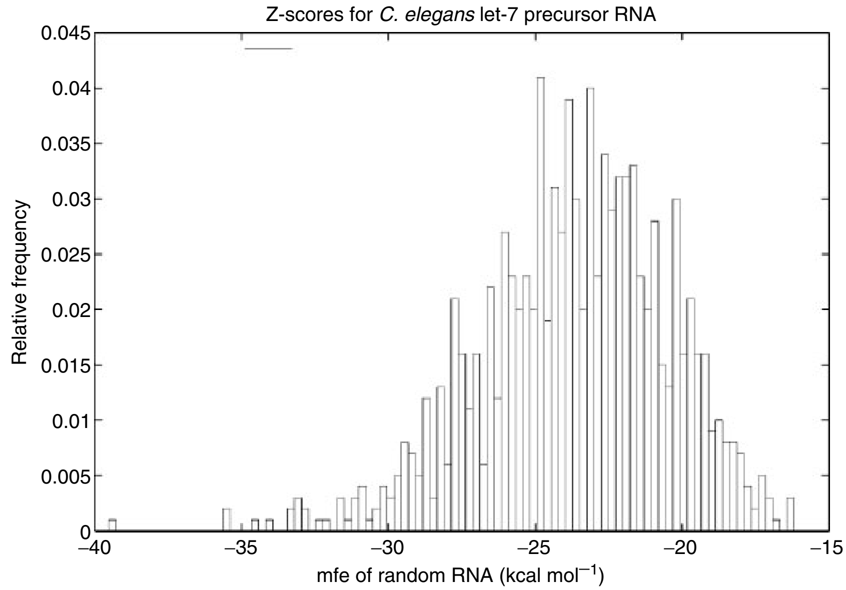

Figure 2 Histogram of the mfe for 1000 random RNAs, each having the same (exact) dinucleotide frequency as that in *C. elegans* let-7 precursor RNA. Mean mfe is −23.54 kcal mol^{-1} with standard deviation 3.23, hence the Z-score for let-7 precursor RNA is $\frac{-42.90-(-23.54)}{3.23}$ or roughly −6. Random RNA produced by the method of Workman and Krogh (1999) as implemented in Clote *et al*. (2005) (minimum free energy computed using `RNAfold`)

or possibly dinucleotide frequencies as that of the window contents (see Workman and Krogh, 1999; Clote *et al*., 2005 for discussion, and Figure 2 for an example). A Z-score of x that is approximately zero means that the mfe of sequence x is indistinguishable from that of its randomizations (i.e., the mfe of a randomization of x is just as often lower as higher than that of x). Similarly, a negative Z-score of x means that the mfe of x is lower than that of most of its randomizations.

Results from Rivas and Eddy (2000) indicate that using Z-score alone is not sufficiently statistically significant to be used to find ncRNA genes. Nevertheless, Washietl *et al*. (2005) combine the use of Z-scores with comparative genomics to develop a remarkably accurate and computationally efficient noncoding RNA gene finder. The authors make novel use of a support vector machine to compute the mean μ and standard deviation σ, rather than relying on slow repeated randomizations of window contents.

Cluster architecture

Chris Dagdigian
BioTeam Inc., Cambridge, MA, USA

1. Clusters

Cluster computing allows mass-market PC and server systems to be networked together to form an extremely cost-effective system capable of handling supercomputer-scale workloads. Cluster sizes can range from two machines up through many thousands of interconnected systems.

Biologists have found that clusters can be used both to expand the scale of existing informatics research efforts as well as to investigate research areas previously written off as prohibitively expensive or computationally infeasible.

The use of the term "cluster" in this article refers to systems operating on the same network or within the same cabinet, datacenter, building, or campus. This differs from "grid computing", which is typically a term associated with the use of many clusters or diverse distributed systems linked together via the Internet or other wide area networking (WAN) technologies. Clusters typically have a single administrative domain, whereas grids can be composed of geographically separated systems and services each of which with its own administrative domain and access policies. The term "Beowulf cluster" typically refers systems purpose-built for parallel computation.

2. Life science cluster characteristics

For maximum utility, flexibility, and capability, scientific and research goals are the primary drivers for cluster architecture decisions. To do otherwise is to risk unintended consequences that limit how the cluster may be used as a research or data processing tool.

The performance characteristics and runtime requirements of the intended scientific application mix play a major role in hardware selection and overall system design. Researchers with a significant need for bioinformatics sequence analysis often find that many of their applications are performance-bound by the amount of physical memory (RAM) in a machine and the speed of underlying storage and I/O subsystems. Users running large parallel applications will find that the speed and latency characteristics of the cluster network will often be the most important factor in optimizing performance and throughput. Some applications including chemistry and molecular modeling codes can be CPU-bound, and run best on systems with

very fast CPUs and high data transfer rates between processor, onboard cache, and external memory.

Understanding the performance-affecting requirements of the scientific application mix is essential when planning new clusters or even upgrading existing systems. Wherever possible, benchmarks reflecting real-world usage and workflows should be performed.

3. Serial or "batch computing" versus parallel computing

Unfortunately, many cluster references, resources, and cluster "kits" are biased toward a process of parallel cluster computing that is not commonly used on many life science settings. A single parallel application is designed to run across many systems simultaneously. The most commonly seen parallel applications are based on PVM (Parallel Virtual Machine) or MPI (Message Passing Interface) standards.

The use of PVM- or MPI-aware parallel applications tends to be rare in the life sciences. The exception tends to be in the areas of molecular modeling and computational chemistry, where there exists a significant body of parallel software available and in use.

A far more common requirement is the need to repeatedly run large numbers of traditional nonparallel scientific applications or algorithms. Each application instance becomes a stand-alone job that can be efficiently scheduled and independently distributed across a cluster.

Large computational biology problems such as bioinformatics sequence analysis fit nicely into this paradigm – every large analysis task is capable of being broken down into individual pieces that can be executed in any order, independent of any other segment. This approach is known as "serial" or "batch" computing. Problems that can be broken up for serial or batch distribution across a cluster are also referred to as "embarrassingly parallel" problems.

The workflow bias toward serial computing rather than parallel computing is one of the main distinguishing characteristics of life science clusters.

4. Cluster topology

Clusters tend to use variations on a "portal" architecture in which all of the cluster compute nodes are kept isolated on a private network (Figure 1). Management and usage of the cluster is achieved via use of a machine that is attached to both the public organizational network and the private cluster network. Additional servers, storage devices, database servers, and management servers are also "multi-homed" to both networks as needed.

A schematic representation of the portal style cluster architecture is seen in Figure 2.

Advantages of the portal architecture approach include:

- Easier management and administration. Cluster operators are free to control, customize, and modify essential network services such as DHCP, TFTP, PXE, LDAP, NIS, and so on, without affecting the organizational network.

Figure 1 A small bioinformatics research cluster using Apple G4 and Intel Xeon-based server systems

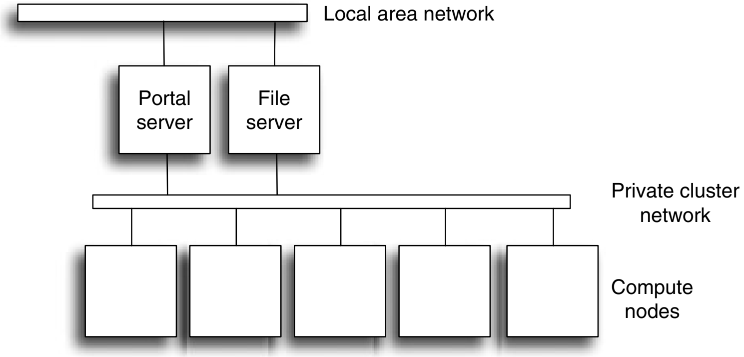

Figure 2 Logical view – portal architecture

- Security and abstraction of computing resources. The architecture prevents large numbers of compute nodes from being directly accessible to the public network. Cluster users are encouraged to think of the cluster nodes as anonymous and interchangeable.

In instances in which jobs running on the cluster may need to communicate with systems or services outside of the cluster (database or LIMS systems, etc.), it is a simple matter to set up NAT (network address translation) or proxy services.

5. Network and interconnects

General-purpose clusters use standard switched Ethernet networking components as the primary method of interconnecting cluster nodes. Some cluster operators find that running a second private "management" network alongside the primary network has administrative advantages. The cost of copper-based Gigabit Ethernet networking products has plummeted to the point where it has become the default choice for clusters of all sizes.

Multiple Gigabit Ethernet links can be "trunked" or bonded together to achieve higher performance. In many cases, the cluster services that best benefit from added bandwidth and network performance capability are cluster file-servers and other data staging or storage systems.

Ethernet networking may not be suitable for all network-dependent tasks and use-cases. In particular, some parallel PVM or MPI applications may be performance limited when run over an Ethernet network due to the relatively high latency between transported packets. Some parallel or global distributed file-system technologies also prefer or may even require the use of a special high-speed, low-latency interconnect.

There are a number of available products and technologies aimed at providing clusters with a higher-performance interconnect. Examples include Myrinet and Infiniband. These can be deployed cluster-wide to complement an existing Ethernet network or deployed to a limited subset of cluster nodes to support parallel applications.

Given the relative lack of latency-sensitive, massively parallel scientific software in the life sciences, the use of interconnect technologies other than Ethernet is quite rare.

6. Distributed resource management

An essential component, especially systems supporting multiple groups or research efforts, is the software layer that handles resource allocation and all aspects of job scheduling and execution across many machines. Generally known as "distributed resource management" (DRM), these software products are critical to successful cluster operation. The most commonly seen DRM products in life science settings are Platform LSF and Sun Grid Engine. Other DRM suites include Portable Batch System (PBS) and Condor. Proper selection and configuration of the DRM software layer is extremely important, as the DRM layer is the "glue" that ties the cluster together.

7. Storage

The most commonly encountered performance-limiting bottleneck in life science clusters is the speed of both local and network-resident storage systems. Network attached storage (NAS) devices providing NFS-based file systems are often used

as a way of making vast amounts of raw research data available for analysis within the cluster. These devices (or the network itself) can quickly be saturated on even moderately busy clusters.

The cost of acquiring a few terabytes of raw NAS can vary by as much as $50 000 USD or more between competitive storage products. Fortunately, the wide price range allows for a healthy ecosystem of differentiated storage products offering different levels of performance, resiliency, cost, and capability.

A popular method of increasing local disk performance in life science clusters involves populating compute nodes with multiple large but inexpensive ATA drives that are mirrored or striped together via software RAID. In addition to vastly increased local I/O performance, these disks can also be used to cache popular databases or files from the central file-server. Very significant amounts of cluster network traffic and file-server load can be eliminated simply by staging data to the local compute nodes prior to launching a large analytical job.

8. Reducing administrative burden

Clusters of loosely interconnected server systems can represent a significant operational challenge. Several inexpensive hardware or software-based methodologies can greatly reduce the amount of effort needed to maintain cluster systems. Approaches include various techniques for performing unattended operating system installations (or reinstallation), remote power control products, and serial console access concentrators.

Relational databases in bioinformatics

Hans-Peter Kriegel, Peer Kröger and Stefan Schönauer
University of Munich, Munich, Germany

1. Introduction

The rapidly growing amount of data in bioinformatics makes the use of a database management system (DBMS) indispensable. Additionally, modern DBMS provide advantages like concurrent multiuser access, security features, and easy web integration.

The relational data model, introduced by Codd in 1970, is the most successful model for DBMS, and is used in numerous commercial products.

2. Relational data management

The relational data model is based on the single concept of relations for data representation. Relations are perceived by the user as tables whose rows are called *tuples* representing the objects. All entries in a column of a table are atomic values from the same domain, and a single column is called an *attribute*. The name of a relation together with its attribute names and domains form the schema of the relation. A minimal subset of the attributes from a relation whose value combination uniquely distinguishes each possible tuple of the relation is called a *key*. Relationships between object sets represented by relations are also stored in tables built from the keys of the relations participating in the relationship. All operations defined on relations take relations as input and generate relations as output. Queries are usually expressed in the Standard Query Language (SQL), which allows data definition as well as data manipulation statements but no procedural elements like loops. Consequently, SQL statements have to be embedded in application programs written in a different programming language.

A sample relational data modeling is illustrated in Figure 1. The example models complexes of proteins. A complex has properties such as name and function and can consist of several proteins. A protein also has properties such as name and function and can participate in several complexes. Thus, two tables "Protein" and "Complex" are generated with particular attributes. Each table specifies attributes

Protein

pID	Name	Function	–
–	–	–	–
101	xyz	Protease	–
–	–	–	–

Complex

cID	Name	Function	–
–	–	–	–
075	abc	null	–
–	–	–	–

Contains

cID	pID
–	–
075	101
–	–

Figure 1 Sample relational model

as primary keys, in this case artificial keys such as "pID" (protein ID) and "cID" (complex ID) for unique identification of its tuples. A further table "Contains" consisting of the primary keys of Complex and Protein links both tables, modeling the relationship between a complex and its contained proteins. A protein may be part of several complexes. Let us note that for some tuples in the tables the value might be unknown, for example, for complex "abc" with cID = 075, the function is not known. In this case, the value is *null*.

A sample query "Find the names of all complexes that contain protein 'xyz'" could be formulated in SQL as follows:

select Complex.name
from Protein, Complex, Contains **where** Protein.name = "xyz"
and Protein.pID = Contains.pID **and** Contains.cID = Complex.cID

3. Advantages

The use of relational DBMSs has several advantages. Owing to its widespread applicability, several commercial and even open-source relational DBMSs are available. With SQL, there exists a standardized and easy-to-learn query language. Several standard interfaces available for SQL allow the integration of databases into web applications or other information systems. Along with the widespread use of relational DBMSs, many powerful tools for such systems were developed, providing support for application development or database administration.

4. Limitations

Although relational databases are frequently used for bioinformatics applications, they cause several major drawbacks, which are described in the following.

4.1. Complex schemas

Bioinformatics research deals with complex objects. These complex objects such as proteins, genes, metabolic pathways, and so on, can often not be modeled adequately with the constructs of relational data models. The resulting data schemas are often rather complex and not intuitive anymore, and thus they are hard to understand and administrate. The information about a single complex biological object is spread over several relations, each describing a single aspect of the object. In addition, data models for bioinformatics databases tend to evolve frequently, increasing the problems of administration.

4.2. Managing biospecific objects

Bioinformatics objects are not only complex to model. Biological entities such as genes and proteins also provide bulky data types that are difficult to model and manage with traditional relational methods. Typically, bulky data types include sequences, for example, nucleotide or amino acid sequences, images, for example, MNR images, set-valued attributes such as molecules consisting of several atoms, and graph- or tree-structured data, for example, pathways or phylogenetic trees. In addition, bioinformatics databases also have to cope with missing attribute values that cannot be adequately and efficiently supported by traditional relational data management concepts.

4.3. Querying

Using SQL is the traditional, most powerful, and most comfortable way to query and extract information from relational databases. To formulate an SQL query, the user must have an overview of the database schema and must know which relations and attributes are relevant for the intended query. Obviously, complex and unintuitive relational schemas are hard to query. Furthermore, in order to manipulate an entire object distributed over several relations, these relations have to be joined during query processing, which is often very time consuming. As a consequence, many bioinformatics databases prevent their users from querying the databases directly using SQL, but instead provide the so-called fixed-form query interfaces. Such fixed-form query interfaces provide a view on the database and allow using a predetermined set of relations and attributes. The queries are allowed only against these interfaces.

5. Discussion

Despite several limitations, relational database management is rather widespread in bioinformatics. Nevertheless, several interesting approaches have been developed recently to cope with the problems and limitations of relational data modeling mentioned above. Some of them are bioinformatics-specific solutions, that is, the

approaches are directly motivated by bioinformatics data management. One of these solutions is ACEDB, a DBMS providing common DBMS features such as concurrency and security features but relying on a data model that is similar to the semistructured data model and thus is more flexible and powerful in the modeling aspect. A further bioinformatics-specific solution is OPM, a commercial suite of tools providing a more powerful, extended object-oriented data model including an appropriate query language and a mapping of such OPM models to standard relational DBMSs. In addition, a more general approach is the concept of object-relational DBMSs, developed for all kinds of applications dealing with complex and spatial objects. An object-relational DBMS provides most features of a traditional relational DBMS but supports object-oriented modeling constructs such as nonatomic attribute types. These systems provide the possibility to specify objects with user-defined attribute types and user-defined functions to determine the behavior of such objects. Via a standard interface, these objects are usually accessible by standard SQL. The advantage of these concepts is that the schemas are less complex since the model is more powerful and expressive than the traditional relational model. Furthermore, the object-relational approach also provides all features of relational DBMSs such as SQL querying, concurrency, query optimization, and so on. The newest versions of DBMSs such as ORACLE, DB2, or MS SQL Server are in fact object-relational DBMSs. However, several bioinformatics databases do not use their features yet.

Basic Techniques and Approaches

Support vector machine software

William Stafford Noble
University of Washington, Seattle, WA, USA

The support vector machine (SVM) (Boser *et al*., 1992; Vapnik, 1998; Cristianini and Shawe-Taylor, 2000) is a supervised learning algorithm, useful for recognizing subtle patterns in complex data sets. The algorithm performs discriminative classification, learning by example to predict the classifications of previously unseen data. The algorithm has been applied in domains as diverse as text categorization, image recognition, and hand-written digit recognition (Cristianini and Shawe-Tyalor, 2000). Recently, SVMs have been applied in numerous bioinformatics domains, including recognition of translation start sites, protein remote homology detection, protein fold recognition, microarray gene expression analysis, functional classification of promoter regions, prediction of protein–protein interactions, and peptide identification from mass spectrometry data (reviewed in Noble (2004)).

The popularity of the SVM algorithm stems from four primary factors. First, the algorithm boasts a strong theoretical foundation, based upon the dual ideas of VC dimension and structural risk minimization (Vapnik, 1998). Second, the SVM algorithm is well-behaved, in the sense that it is guaranteed to find a global minimum and that it scales well to large data sets (Platt, 1999a). Third, the SVM algorithm is flexible, as evidenced by the list of applications above. This flexibility is due in part to the robustness of the algorithm itself, and in part to the parameterization of the SVM via a broad class of functions, called *kernel functions*. The behavior of the SVM can be modified to incorporate prior knowledge of a classification task simply by modifying the underlying kernel function. The fourth and most important explanation for the popularity of the SVM algorithm is its accuracy. Although the underlying theory suggests explanations for the SVM's excellent learning performance, its widespread application is due in large part to the empirical success the algorithm has achieved.

An early successful application of SVMs to biological data involved the classification of microarray gene expression data. Brown *et al*. (2000) used SVMs to classify yeast genes into functional categories on the basis of their expression profiles across a collection of 79 experimental conditions (Eisen *et al*., 1998). Figure 1 shows a subset of the data set, divided into genes whose protein products participate and do not participate in the cytoplasmic ribosome. The ribosomal genes show a clear pattern, which the SVM is able to learn relatively easily. The SVM solution is a hyperplane in the 79-dimensional expression space. Subsequently, a

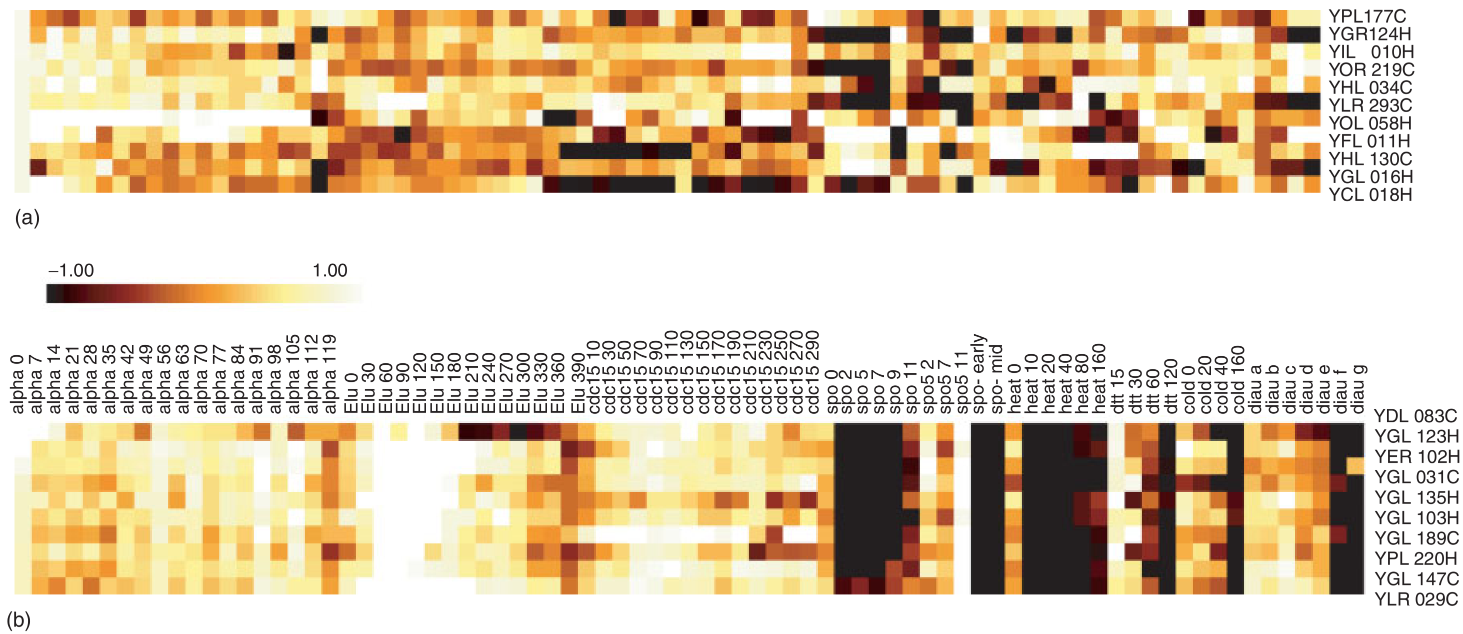

Figure 1 Gene expression profiles of ribosomal and nonribosomal genes. The figure is a heat map representation of the expression profiles of 20 randomly selected genes. Values in the matrix are log ratios of the two channels on the array. The upper 10 genes are from the "cytoplasmic ribosomal" class in the MIPS Yeast Genome Database, as listed at **www.cse.ucsc.edu/research/compbio/genex/genex.html**. An SVM can learn to differentiate between the characteristic gene expression pattern of ribosomal proteins and non-ribosomal proteins. The figure was produced using matrix2png (Pavlidis P and Noble WS (2003) Matrix2png: A utility for visualizing matrix data. *Bioinformatics*, **19**(2), 295–296)

given gene's protein product can be predicted to localize within or outside the ribosome, depending upon the location of that gene's expression profile with respect to the SVM hyperplane. SVMs have also been used successfully to classify along the other dimension of gene expression data: placing entire gene expression experiments into categories on the basis of, for example, the disease state of the individual from which the expression profile was derived (Furey *et al*., 2001; Ramaswamy *et al*., 2001; Segal *et al*., 2003).

A scientist who wishes to apply support vector machine learning to a particular biological problem faces first the question of which kernel function to apply to the data. Essentially, the kernel function defines a notion of similarity between pairs of objects. In the case of gene expression data, for example, the kernel value for two genes with similar expression profiles will be large, and vice versa. Mathematically, the kernel function must follow certain rules in order for the SVM optimization to work properly. Specifically, the kernel must be positive semidefinite, meaning that, for any given data set, the square matrix of pairwise kernel values defined from that data set will have nonnegative eigenvalues. In practice, however, most users of SVM software do not have to worry about these mathematical details, because the software typically provides a relatively small collection of valid kernel functions to choose from.

In general, a good rule of thumb for kernel selection is to start simple. The simplest kernel function is a linear scalar product, in which the products of corresponding elements in each of the two items being compared are summed. Normalizing the kernel, which amounts to projecting the data onto a unit sphere, is almost always a good idea. Centering the kernel, so that the points lie around the origin, is also helpful, though this operation is difficult to perform properly if the (unlabeled) test data is not available during training.

A slightly more complex class of kernel functions is the set of polynomials, in which the scalar product is raised to a positive power. The degree of the polynomial specifies the n-way correlations that the kernel takes into account. Thus, for the 79-element gene expression data mentioned above, a quadratic kernel implicitly accounts for all $79 \times 79 = 6241$ possible pairwise correlations among expression measurements. Obviously, as the polynomial degree gets larger, the number of features increases exponentially, eventually overwhelming the SVM's learning ability. It is necessary, therefore, to hold out a portion of the labeled data from the training phase and to use that data to evaluate the quality of the trained SVM with different kernels. The use of a hold-out set is the basis of a more general technique known as *cross-validation* (Duda and Hart, 1973). Figure 2 shows the effect of the polynomial degree on the SVM's ability to recognize members of the cytoplasmic ribosomal proteins. As the degree increases, accuracy improves slightly, but then drops again when the number of features becomes too large.

Besides polynomial kernels, the other common kernel is the radial basis function. This kernel warps the space where the data resides by putting a Gaussian over every data point. The kernel then measures similarities in that warped space. In this case, the user-controlled parameter is the width of this Gaussian. Like the polynomial degree parameter, the Gaussian width is typically selected via cross-validation. Some software will automatically select a reasonable (though not

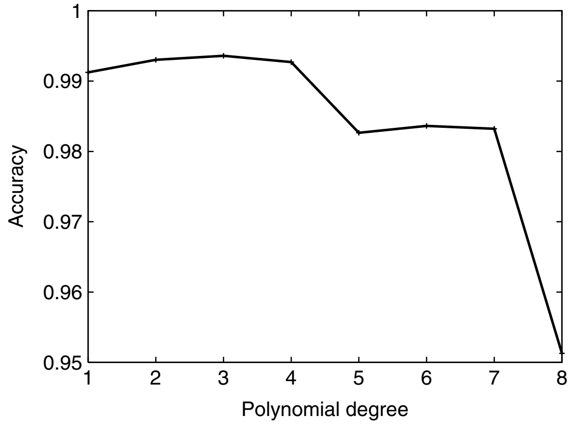

Figure 2 The effect of polynomial degree on SVM performance. The figure plots the classification accuracy of an SVM as a function of the polynomial degree. The SVM was trained to recognize ribosomal proteins, using data from Brown MPS, Grundy WN, Lin D, Cristianini N, Sugnet C, Furey TS, Ares Jr M and Haussler D (2000) Knowledge-based analysis of microarray gene expression data using support vector machines. *Proceedings of the National Academy of Sciences of the United States of America*, **97**(1), 262–267 and using the Gist software with default parameters. Accuracy was measured using threefold cross-validation, repeated five times

necessarily optimal) width by examining the average distance between positive and negative examples in the training set.

The kernels discussed so far are applicable only to vector data, in which each object being classified can be represented as a fixed-length vector of real numbers. Gene expression data fits this paradigm, but many other types of biological data – protein sequences, promoter regions, protein–protein interaction data, and so on – do not. Often, it is possible to define a relatively simple kernel function from nonvector data by explicitly constructing a vector representation from the nonvector data and applying a linear kernel. For example, a protein can be represented as a vector of pairwise sequence comparison (BLAST or Smith–Waterman) scores with respect to a fixed set of proteins (Liao and Noble, 2002) or simply as a vector of 1's and 0's, indicating the presence or absence of all possible length-k substrings within that protein (Leslie *et al*., 2002). Similarly, protein–protein interaction data for a given protein can be summarized simply as a vector of 1's and 0's, where each bit indicates whether the protein interacts with one other protein. Other, more complex kernels, such as the diffusion kernel (Kondor and Lafferty, 2002), can also be constructed without relying upon an explicit vector representation. In general, selecting the kernel function is analogous to selecting a prior when building a Bayesian model. Thus, while simple kernels often work reasonably well, much research focuses on the development of complex kernel functions that incorporate domain knowledge about particular types of biological data.

In addition to selecting the kernel function, the user must also set a parameter that controls the penalty for misclassifications made during the SVM training phase. For a noise-free data set, in which no overlap is expected between the two classes being discriminated, a hard margin SVM can be employed. In this case,

the hyperplane that the SVM finds must perfectly separate the two classes, with no example falling on the wrong side. In practice, however, it is often the case that some small percentage of the training set samples are measured poorly or are improperly labeled. In such situations, the hard margin SVM will fail to find any separating hyperplane, and a soft margin must be employed instead. The soft margin incorporates a penalty term, and penalties are assigned to each misclassified point proportional to the point's distance from the hyperplane. Thus, a misclassified point that is close to the hyperplane will receive a small penalty, and vice versa. SVM practitioners differ over whether a linear (1-norm) or quadratic (2-norm) penalty yields better performance in general; however, regardless of the type of penalty imposed, the proper magnitude of the penalty is definitely problem-specific. Hence, this penalty parameter is typically selected either using cross-validation or by minimizing the number of support vectors (i.e., nonzero weights) in the SVM training output. The effect of this soft margin parameter on SVM accuracy is typically large, outweighing the effect, for example, of polynomial degree shown in Figure 2.

Setting the soft margin parameter is further complicated when the relative sizes of the two groups of data being discriminated are skewed. In many pattern recognition problems, this type of skew is typical: the interesting (positive) class of examples is small, and it is being discriminated from a relatively large (negative) class of uninteresting examples. In such a situation, the soft margin must be modified to asymmetrically penalize errors in the two classes: making a mistake on one of the relatively few positive examples is much worse than making a mistake on one of the many negative examples. A reasonable heuristic is to scale the penalty according to the relative class sizes. Hence, if there are 10 times as many negative examples as positive examples, then each positive misclassification receives 10 times as much penalty. In general, the degree of asymmetry should depend upon the relative cost associated with false-positive and false-negative predictions.

So far, we have discussed the SVM only in the context of discriminating between two classes of examples (e.g., ribosomal and nonribosomal genes). Many prospective SVM users worry that the binary nature of the algorithm is a fundamental limitation. This is not the case. Generalizing the SVM to perform multiclass pattern recognition is trivial. The most straightforward, and often the most successful, means of carrying out this generalization is via a so-called one-versus-all training paradigm. In order to discriminate among n different classes of examples, n SVMs are trained independently. Each SVM learns to differentiate between one class and all of the other classes. A new object is classified by running it through each of the SVMs and finding the one that produces the largest output value. This approach has been used successfully, for example, to classify 14 types of cancer from gene expression profiles (Ramaswamy *et al*., 2001).

Finally, a desirable feature of any classification algorithm is the ability to produce probabilistic outputs. In general, an SVM produces a prediction that has no units. This discriminant score is proportional to the example's distance from the hyperplane, so a large positive value implies high confidence that the example lies in the positive class. A relatively simple postprocessing step involving fitting a sigmoid curve can convert these discriminants to probabilities (Platt, 1999b).

Perhaps the easiest way for a novice to apply an SVM to a particular data set is via the web interface at **svm.sdsc.edu**. This server allows for the training of an

SVM on a labeled data set. The SVM can then be used to make predictions on a second, unlabeled data set. Additional flexibility, including leave-one-out cross-validation and empirical curve fitting to get probabilistic outputs, is available by downloading the underlying Gist software (**microarray.cpmc.columbia.edu/gist**) (Pavlidis *et al*., 2004). Many other SVM implementations are available in the "Software" section of **www.kernel-machines.org**. Among these, perhaps the most popular is SVMlight (**svmlight.joachims.org**), which implements a generalization of the fast sequential minimal optimization algorithm (Platt, 1999a) and also offers a range of features. Other popular implementations include mySVM (**www-ai.cs.uni-dortmund.de/SOFTWARE/MYSVM**), SVMTorch (**www.torch.ch**), and libSVM (**www.csie.ntu.edu.tw/~cjlin/libsvm**).

Brief Python tutorial for bioinformatics

Michael Poidinger
Johnson and Johnson Research Pty Ltd, Sydney, Australia

1. Introduction

Python is an interpreted, interactive, object-orientated programming language first created and released by Guido van Rossen in 1989–1991. It is called Python after the BBC comedy series, "Monty Pythons's Flying Circus". Python is currently an open source software project, which freely welcomes anyone with an interest in the language to contribute to it. The primary source of information concerning Python can be found at **www.python.org**, which includes downloads of the most recent release of the language (2.3.4) for all major operating systems. Other references to bioinformatic scripting in general and Python in particular can be found in this encyclopedia in other article references (*see* Article 103, **Using the Python programming language for bioinformatics**, Volume 8, Article 112, **A brief Perl tutorial for bioinformatics**, Volume 8, and Article 104, **Perl in bioinformatics**, Volume 8).

2. Language basics

Python uses a natural language syntax and indentation to delineate code blocks (as opposed to {} brackets used by most other programming languages). Control statements are terminated by a colon. Python is case sensitive, x and X could be the names of different variables. Python is a dynamically/implicitly typed language, which means that variables do not need to be formally declared at compile time. Variables can also be reused to hold any type of data during the runtime of the program. The Python interpreter can be run in interactive mode, either from a Unix style command line or by running pythonwin in Win32. This shell is exited with control-D. Inside the interpreter, lines are prefixed by `">>>"`. A Python script can be run by passing it as a parameter to the Python command. The –i parameter will invoke the interactive interpreter after script execution.

For example, assume that the script myscript.py contains the line x = 1:

```
python -i myscript.py
>>>print x
1
```

Basic data types: Python has four basic data types: numbers, strings, 0-based arrays, and dictionaries (hash tables). Literal strings can be enclosed by either single or double quotes. There are two types of arrays: mutable lists (contents can be changed after instantiation) and immutable tuples.

Assignment uses the = operator:

```
x = "hello world" #string
x = 1 #integer
x = anObject #user defined/built-in object
x = aMethod #user defined/built-in method
x = [1,"hello world",anObject,aMethod] #a list
x = (1,"hello world",anObject,aMethod) #a tuple
x = {1: 1, 2: "hello world", 3: anObject, 4: aMethod} #a dictionary
```

```
Note: Because Python is dynamically typed, the above 7 lines
would be valid as successive lines of a Python program

alternative dictionary implementation
x = {}
x[1] = 1
x[2] = "hello world"
x[3] = anObject
x[4] = aMethod
dictionary keys and values can be any valid Python data type,
including user defined.
```

3. Basic data manipulation

Strings and arrays can be sliced, which means you can extract the *n*th element or the *m*th to *n*th element.

```
python
>>>x = "hello world"
>>>y = ["h","e","l","l","o"," ","w","o","r","l","d"]
>>>print x[0]
h
>>>print y[0]
h
>>>print x[6:8]
wo
print y[6:8]
["w","o"]
```

Strings can be instantiated with % substitution

```
assume v1 is a string and v2 is an integer

In other languages:
myString = "hello" + v1 + "world" + str(v2)

same example using % substitution
myString = "hello %s world %d" % (v1, v2)
```

File handlers can be assigned using the built-in open function. Files can be opened in read (r), write (w), append (a), and binary (b) modes. r is the default mode.

```
fh = open("myfile.txt", "w") #open file for writing
fh = open("myfile.jpg", "rb") #open file for binary reading
fh = open("myfile.txt") #open file for reading
x = fh.read() #assign the entire contents of the file as a
    string to x
x = fh.readline() #assign the first line of the file as a
    string to x
x = fh.readlines() #assign the entire contents as a list of
    lines to x
fh.write("hello world") #write hello world to a file opened for
writing
```

Variables can be assigned a null/nil value with the keyword None.
Boolean operators: Python uses natural language : and, or, not, in.
Equality operators: == (equals), != (not equals), < (less than), > (greater than).

```
if (x != 2 or y <  = 3) and not (z == 4 or w in [1,2,3]):
```

Any variable can be used in a boolean statement. None, False, “”, 0, [], and () equate to false, any other value equates to true. The boolean types True and False can also be used.

```
if x:
    #do this code if x is true
else:
    #do this code if x is 0, "", [], (), None or False
```

4. Importing modules

External Python modules are imported using the `import` key word. Modules can be any other Python scripts written by anyone, defined modules that come with the language, or third-party modules downloaded and compiled into the Python program. Paths to Python modules in the first case can be defined either with the environment variable PYTHONPATH or at runtime using the path function of

the sys module (see below). Import statements can occur anywhere in Python code (including inside if ... else statements). There are two syntaxes for the import statement, which affect how members of the module are referenced. The following example assumes a file called mymodule.py, which is located in mydirectory/mypythonscripts.

```
import sys
sys.path.append("mydirectory/mypythonscripts")
import mymodule
x = mymodule.myfunction()

from mymodule import myfunction
x = myfunction()
```

You can also use * to reference everything in a module.

```
from mymodule import *
x = myfunction()
```

5. Control statements

Python uses if ... elif ... else, for and while for execution control.

```
for i in range(0,100,2): #for each number from 0 to 99,
increment by 2
for item in [item1, item2, item3]:

while x > 3:

if x > 3:
     #code block 1
elif x < 1:
     #code block 2
else:
     #code block 3
```

While and for loops can be exited with the `break` statement.

```
fh = open("myfile.txt")
while 1: #always true
     line = fh.readline()
     if not line: #line is an empty string if at end of file
          break #exit the while loop
```

Python uses `class` to define a new class, and `def` to define a function/subroutine or class method. Function parameters can be assigned a default value,

and those parameters with default values are optionally passed to the function when called.

```
python
>>>def increment(value, inc=1):
... return value + inc
...
>>> print increment(2)
3
>>>print increment(2,3)
5
>>>print increment(2, inc=3)
5
```

Class syntax is shown in the examples below. Python has no concept of class scope, such as private or protected, as found in languages such as Java. It is common to use single or double underscore prefixes as a "reminder" that a method has restricted scope, but this rule is not enforced by Python. You can overload built-in functions using methods both prefixed and suffixed by double underscores; examples are given below. Class methods always receive the keyword self as the first parameter; class attributes and methods are also referenced within the class by the self keyword.

Python is inherently reflective. Variables and functions can be accessed through the built-in locals() and globals() functions, which return dictionaries of all elements of the script. Classes can be manipulated with the hasattr, getattr, and setattr built-in methods. Examples of these are below.

6. Python bioinformatic resources

There is an open source project located at **www.biopython.org**, which contains a large number of script and class modules to handle biological data and which acts as a framework for building your own programs. A short example is shown in the examples section.

7. Examples

The following example scripts display the flexibility of the Python language for building useful code for biological data manipulation. The code can be cut and pasted into files, as indicated.

```
#--------------------cut & paste into a file called bioclasses.
py------
import string

class CodonTable:
```

```
    def __init__(self):
         self.codons = {}
         self.codons["AAA"] = "L"
         self.codons["AAC"] = "N"
         self.codons["GGG"] = "G"
         self.codons["TAA"] = "*"
    #table not finished due to space limitations

    def getResidue(self, codon):
         if self.codons.has_key(codon):
              return self.codons[codon]
         else:
       return "?"

class Writeable:
#a basic class which allows an object to be written to a file

     def write(self, fh, format, lineLength = -1):
     #method parameters:
     #fh : a file handle
     #format : a string representing the format
     #lineLength : optional integer indicating number of characters
     #on a line
         method = "_as%s%s" % (string.upper(format[0]),format[1:])
         #The method variable will be assigned the string:
         #_as + uppercase first letter of format + rest of format

         if hasattr(self, method):
         #if format == "fasta" then method == "asFasta"
         #hasattr will test for the existence of the asFasta method
              data = getattr(self, method)(lineLength)
              fh.write(data)
         else:

        result = Gene(subName, subSeq)
        return result
#----------------end file bioclasses.py---------------------

#------cut and paste into a file called biorun.py--------------------

#ideally, the information for a gene would be derived from
#a GenBank or similar record that has been parsed. For this
#example, the information will be artificially created

import bioclasses

c1 = "AAAAAAAAC"
c2 = "GGGAAAGGGAACAAAGGG"
c3 = "GGGAACAAAGGGAAAAACTAA"
#3 codons

i1 = "CTGCGCGCTAAGATCGCT"
i2 = "CGCTAGAGCTCGGGAATAGCGCTA"
#introns

seq = c1 + i1 + c2 + i2 + c3

gene = bioclasses.Gene("test", seq)

marker = 0
gene.setExon(marker, len(c1))
#This will be the 0th exon in the object exon list

marker = len(c1) + len(i1)
gene.setExon(marker, marker + len(c2))
#This will be the 1st exon in the object exon list

marker = marker + len(c2) + len(i2)
gene.setExon(marker, marker + len(c3))
#This will be the 2nd exon in the object exon list

gene.setTranscript((0,1))
#1st transcript comprises exons 0 and 1
gene.setTranscript((0,2))
```

```
gene.setTranscript((0,1,2))

cTable = bioclasses.CodonTable()

print gene.getPeptide(0, cTable)
print gene.getPeptide(1, cTable)
print gene.getPeptide(2, cTable)

#some examples of overloading, and reflection

sub1 = gene[10]          #use the __getitem__ method
sub2 = gene[10:]         #which overwrites the slice operator
sub3 = gene[10:20]
subList = [sub1, sub2, sub3]   #make a list of subsequences

fh = open("sequences.txt","w")  #open a file for writing
for s in subList:
     s.write(fh, "fasta",20)          #use the write method
                                #of the parent class

s.write(fh, "staden",20)
fh.close()

#-------------------end file biorun.py-------------------------
```

Running the biorun script (Python biorun.py from the command line) will produce the following output (from the print statements):

```
LLNGNLGLN*
LLNGLGNLG
LLNGLGNLGGNLGLN*
Don't know how to generate staden format
```

It will also produce a file called “sequences.txt,” which contains the following:

```
>test_10
T
>test_10_2147483647
TGCGCGCTAAGATCGCTGGG
AAAGGGAACAAAGGGCGCTA
GAGCTCGGGAATAGCGCTAG
GGAACAAAGGGAAAAACTAA
>test_10_20
TGCGCGCTAA
```

8. Biopython example

The following is paraphrased from **www.biopython.org/docs/tutorial/Tutorial004.html**

Assuming that you have downloaded and installed the Biopython modules from **www.biopython.org** and that you have a local copy of a blast search,

```
from Bio.Blast import NCBIStandalone
#import the relevant part of Biopython

blastFH = open('my_file_of_blast_output', 'r')
#create a file handle to your blast result

bParser = NCBIStandalone.BlastParser()
#instantiate a parser

bRecord = bParser.parse(blastFH)
#Create a blast record object from your file

#That's pretty much it. Now you can manipulate the
#record object to display the different sections
#of the blast file.

#for instance, to see all the alignments with Evalue < = 0.04...

E_VALUE_THRESH = 0.04

for alignment in bRecord.alignments:
    for hsp in alignment.hsps:
        if hsp.expect <  E_VALUE_THRESH:
           print '****Alignment****'
           print 'sequence:', alignment.title
           print 'length:', alignment.length
           print 'e value:', hsp.expect
           print hsp.query[0:75] + '...'
           print hsp.match[0:75] + '...'
           print hsp.sbjct[0:75] + '...'
```

A brief Perl tutorial for bioinformatics

Michael J. Moorhouse
Erasmus MC, Rotterdam, The Netherlands

1. Introduction

This tutorial gives an introduction to programming in the Perl programming language by covering the basic syntax and key concepts important in two examples of Perl. For a review of Perl and its use in the Bioinformatics and Bioscience, Article 104, **Perl in bioinformatics**, Volume 8 (*also see* Article 103, **Using the Python programming language for bioinformatics**, Volume 8). Presented first is an overview of Perl syntax and key concepts. More extensive documentation can be accessed by running "perldoc perl" with a default installation of the Perl or from the excellent on-line resource: **http://www.perldoc.com**.

2. Perl syntax and concepts

The conversion of the human readable source code, listed in (say) file foo.pl, to machine executable format is made by the Perl runtime system. This can be done in two ways:

1. Calling the Perl interpreter (e.g., /usr/bin/perl on some Unix systems) on the command line with the source code file name.
2. On Unix systems, setting the executable flag on the source code file and including a line starting with "#!" followed by the path to the Perl interpreter (e.g., #! /usr/bin/perl). Technically, Perl is interpreted language that is then executed in a runtime system rather than being compiled.

In Perl, there are three basic datatypes (see the "perlvar" manual page for more information on these):

1. "Scalars" that store numbers (integers or floating point), characters, strings or a combination of these. These are referred using a "$" symbol.
2. "Arrays of scalars", which are ordered sets of scalars variables. The array as a whole is referred to using the "@" symbol and the individual elements using the scalar "$" symbol (as these are scalars).

3. “Hash (or associative) arrays”, which store scalar values that are referred to using keys with no assumed order between the key-value pairings. The entire array is referred to using the “%” symbol and the values using the scalar “$”.

Owing to its history as a scripting/text processing language, Perl has very good file-handling capabilities. These are complemented by inbuilt POSIX compliant regular expressions that allow the flexible matching of text patterns.

It is very easy to run through all the files passed on the command line or the text stream passed via the standard input (STDIN) and search for occurrences in the string “kinase” is very easy:

```
while (<>) #Iterates through each line of the file / STDIN
      {
#'kinase' found in $_ (special variable meaning "current line")?
      if (/kinase/)
            {print "$_";}    #If so, print the line
      }                      #Otherwise, do nothing and load next line
```

Certain “metacharacters” can be used to match specific features of text, for example:

- “.” matches “any character” (apart from new line characters: “\n” for Unix, “\r\n” for Microsoft Windows or “\r” for Apple Macintosh).
- “ ^ ” means “the start of the string”.
- “*” means “zero or more characters”. A useful modifier here is “*?”, which means “match the shortest string possible rather than the longest”.
- “$” means “end of line” (or end of the string depending on the context).

A more complete list is giving the “perlre” manpage.

Regular expressions are also useful for “capturing” data using brackets “()” to store a particular section of text matched.

For example,

```
(my $GO_ID, my $Description, my $Type) = m/^(GO:.*?)\t(.*?)\t(.)/;
```

which when scanning the text

```
"GO:0000001     mitochondrion inheritance     P"
```

results in the text being split into its component parts and the substrings being placed into the correct scalar variables.

Substituting strings is also easy using the “s/ / /” construct, for example

```
$Test = "Bioinformatics";
$Test =~ s/informatics/science/;
$Test is now "Bioscience"
```

Also useful are standard solutions to common regex tasks that have been developed, as in the following example, which converts the string into lower case text with the start of each word in upper case (see "perlfaq4" for a fuller discussion or the "Text::Autoformat", which does better "title case" capitalization):

```
$Description =~ s/(\w+)/\u\L$1/g;
```

3. Program 1 – basic Perl

This example demonstrates the basic features and syntax of Perl: variable declaration, conditional tests, iterative loops, and the two types of array access (Hash and Index) (see Figure 1a).

When run, the program checks IDs supplied on the command line against the list downloaded from the Gene Ontology consortium (Ashburner *et al*., 2000; Harris *et al*., 2004), and prints out the human readable text for those recognized as valid. (*See also* Article 82, **The Gene Ontology project**, Volume 8, Article 83, **Ontologies for information retrieval**, Volume 8.) The output is shown in Figure 1(b).

4. Program 2 – graphical BioPerl

This example demonstrates the use of the Bio::Graphics module, which plots the positions of features in a section of DNA in the form of an image (Stajich *et al*., 2002). See Figure 2(b) for the image and Figure 2(a) for the source code.

As Perl has no native graphic drawing capabilities, Bio::Graphics uses the external gd-lib drawing library (written in "C" and coded by Tom Boutell, see **http://www.boutell.com/gd**) via the GD.pm Perl interface coded by Lincoln Stein (see **http://stein.cshl.org/WWW/software/GD/**). GD.pm is a generic image creation library that supplies a set of functions "graphics primitives" that can draw lines, arcs, rectangles, polygons, and other simple image manipulation tasks, harnessed by Bio::Graphics to produce a more complex display. This is as used in the "Ensembl" genome browser to visualize the location of "features" (genes, exons, mutation sites, etc.) (Birney *et al*., 2004).

For this example to run, you need the GD.pm module and the GD Library installed on your system along with the libpng and zlib "C" libraries needed by GD.

The biological data displayed in this example are the protein coding regions of entry "ISTN501" in the EMBL database (Brown *et al*., 1983; Nascimento and Chartone-Souza, 2003), see Table 1.

This contains the Tn501 transposon, which codes for the biological Mercury detoxification system (aka. the "Mer Operon"). This is studied in depth in "Bioinformatics, Biocomputing and Perl" written by Moorhouse and Barry.

The example demonstrates two important points:

1. The power of modules and how to call them.

```
#!/usr/bin/perl
#
use strict;     #Force declarations of variables (using 'my') before use

my $GO_List = shift;   #Recover list from 1st Command Line argument
unless (-e $ARGV[0]) {die "Cannot continue without file: '$ARGV[0]'\n"; }
$GO_List =~ s/ //g;    #Remove any spaces user might have added
my @GO_List = split (",",$GO_List);   #Split list in an index array '@GO_List' on commas

my %GO_Lookup_Table;   #Create hash array to store GO ID -> Text mappings
while (<>)                      #Cycle through remaining file:
        {                       #each line is loaded in '$_'
        if (/^!/) {next;}       #Skip all header lines (tests '$_' implicitly using regex)
#Use regex captured parts of line between '()' to variables $GO_ID, $Description and
$Type
        (my $GO_ID, my $Description, my $Type) = m/^(GO:.*?)\t(.*?)\t(.)/;
        unless ($Type eq "P") {next;}  #Check if GO Term is of type "biological process"
        $Description =~ s/(\w+)/\u\L$1/g;#Complex regex to capitalize text (see perlfaq4)
        $GO_Lookup_Table {$GO_ID} = $Description;    #Populate the hash array
        }
#Run through '@GO_List' one ID, '$Current_GO_ID', at a time:
foreach my $Current_GO_ID (@GO_List)
        {
        if (exists $GO_Lookup_Table{$Current_GO_ID}) #Was the ID one found in the file?
                {                               #Yes it was, so print out the term:
                print "$Current_GO_ID\t:\t'",$GO_Lookup_Table{$Current_GO_ID},"'\n"
                }
                else                            #No it was not, so note this:
                {print "'$Current_GO_ID'\t- NOT FOUND!\n";}
        }       #Move on to next @GO_ID / '$Current_GO_ID'
```

(a)

```
GO:0000025     :       'Maltose Catabolism'
GO:0000002     :       'Mitochondrial Genome Maintenance'
'GO:9999999'   - NOT FOUND!
```

(b)

Figure 1 (a) Source code of Program #1. This “looks-up” the textual description of GO ID. Syntax highlighting, based on the styles used in ‘nedit’ editor program has been used to make the code more readable. (b) Output for Program #1 as run in October 2004 (results may vary slightly due to continual updating of the GO)

```
#!/usr/bin/perl

# This is code example 1 in the Graphics-HOWTO
use strict;
use Bio::Graphics;
use Bio::SeqFeature::Generic;

my $panel = Bio::Graphics::Panel->new(-length => 8000,-width  => 800);
my $track = $panel->add_track(-glyph => 'generic',-label  => 1);

while (<>) { # read blast file
  chomp;
  next if /^\#/;  # ignore comments
  my($name,$score,$start,$end) = split /\t+/;
  my $feature = Bio::SeqFeature::Generic->new(-display_name=>$name,-score=>$score,-
start=>$start,-end=>$end);
  $track->add_feature($feature);
}
open OUT, ">panel.png";
print OUT $panel->png;
close OUT;
```

(a)

(b)

Figure 2 (a) Source code of Program #2. This is a fully functional program fragment: See text for description. Syntax highlighting as in the first program, in Figure 1(a). (b) Output of Program #2. This uses the Bio::Graphics 'BioPerl' module

Table 1 Input file/table for program #2. These data are the extracted protein coding regions for the 'Tn501' Operon

#EMBL Original File: 'ISTN501'			
#Gene	Score	Start	End
MerR	0	114	548
MerT	0	620	970
MerP	0	983	1258
MerA	0	1330	3015
MerD	0	3033	3398
MerE	0	3395	3631
ORF2	0	3628	4617
TnpR	0	4792	5352
TnpA	0	5356	8322

Drawing the graphic shown in Figure 2a is very easy because the complexity is contained in the Perl modules and the underlying libraries they call. The two lines:

```
use Bio::Graphics;
use Bio::SeqFeature::Generic;
```

instruct Perl to expect calls to subroutines and data objects contained in these modules. The "::" syntax denotes the organizational hierarchy of the module and allows either all the features of the module to be accessible (in the first case above) or just a subset (as in the second case).
The ultimate result is a simple interface that leaves the programmer free to concentrate on data manipulation rather than on rudimentary layout of the graphics primitives.

2. The object orientated syntax of Perl, for example:

```
my $feature = Bio::SeqFeature::Generic->new(-
display_name=>$name,-score=>$score, -start=>$start, -
end=>$end);
```

is of the generic type:

```
my Handle = Module::SubModule::Function -> new (hash array
containing parameter list);
```

often used by modules. If you wish to code extensively using other modules, such as GD.pm, you will need to understand the basics of his syntax, but with this, it is easy to get started.

The Bio::Graphics module is far more capable than presented here; see the online tutorial at **http://bioperl.org/HOWTOs/html/Graphics-HOWTO.html**.

5. Summary

Perl is widely used in Bioinformatics today because it is easy to use and it has a wide variety of extra code modules – many of which have been developed to solve Bioinformatics tasks. The appeal of Perl seems to be a combination of the ease of programming, excellent native support for text handling and the extensive stock of modules that exists. Perl really is a biological "gem".

Tutorial

Grid technologies

Douglas W. O'Neal
Delaware Biotechnology Institute, Newark, DE, US

In their 1998 book *The Grid*: *Blueprint for a New Computing Infrastructure*, Foster and Kesselman gave an initial definition of a grid: "A computational grid is a hardware and software infrastructure that provides dependable, consistent, pervasive, and inexpensive access to high-end computational capabilities" (Foster and Kesselman, 1998). This definition is built on earlier applications in metacomputing and network-aware applications and is general enough to encompass several types of grids in existence today. The analogy commonly used to describe grid computing is to a power grid. When an appliance is plugged into a matching receptacle, it is understood that the power of the correct voltage will be immediately available. How that power is generated and delivered may not be known to the end user and the complexity of the system is irrelevant to the functioning of the appliance. This vision translates to a view of a virtual computer that provides unlimited capacity on demand without regard to the complexity of the underlying hardware.

Capacity can be measured in multiple ways and grids can be developed to match the requirements. The most common grids in existence today fall into the categories summarized below. These types are not strict definitions and any given grid may combine characteristics of several of these.

1. Computational grid

This is the most commonly considered grid, primarily using high-performance servers and/or clusters of systems to deliver raw computational power. A job may make use of this grid's resources in different ways depending on the job's algorithms. The easiest is to just have the grid find an available high-performance system on which to run the job instead of using the local resources. Second, if the job can be split into several independent pieces, then each piece can be sent to a different processor and the results merged after the last piece is finished. The third way is the most involved and is where the application is redesigned to work in parallel on multiple processors in the grid.

2. Data grid

This type of grid provides for the storage and retrieval of data in a secure and reliable manner. Data may be replicated across multiple sites, with access granted to other organizations. The grid manages the data storage, grants access to authorized users, and provides update procedures for multiple writers.

3. Communications grid

High-bandwidth communication within a grid is a necessary component for the utilization of other resources. For example, a job may be processing a large data set through multiple passes and the data set may not be local to the machine running the job. External communications to the Internet may be the primary purpose of a grid. Services such as search engines have large bandwidth and redundancy requirements that can be met through a grid with multiple external Internet connections.

4. Scavenging grid

This is a special case of a computational grid in which unused computing resources from desktop systems are harvested. The use of these machines may be limited to after business hours to minimize the impact on the users of the systems. SETI@Home (2006) and similar projects also scavenge central processing unit (CPU) cycles while a desktop system is otherwise idle.

For any grid, there are several basic requirements that must be met. All have a technological base but some also have political overtones. These core technologies include the following:

5. User authentication and authorization

The first steps in accessing resources on the grid are identifying yourself to the system and determining to which resources you are allowed access. The first of these is authentication, a process that needs to be made a single time per session and then propagated to any resource used in that session. The second is authorization – a more difficult issue. Given that organizations tend to be protective of the resources they contribute to the grid, the granting of these resources to others is a social, business, and, possibly, a legal issue.

6. Resource discovery

Services on the grid must not only be made available but their availability must be made known to the potential users of those services. Since systems are frequently entering or leaving the grid, this list of available resources must be managed dynamically. Usage of the resources needs to be tracked for both accounting purposes and for scheduling.

7. Resource management/scheduling

At the most basic level, this involves the actual allocation of resources to specific jobs. Allocation rules may take into account the user's authorization level, priorities given to the user, previous usage patterns, and resource requirements such as memory needed, expected run time, or a hardware platform. Scheduling may also be included in order to have the necessary resources available for a process that may need to run at a certain time or to be able to block off large amounts of resources.

8. Data management

In a grid, it is unlikely that data will be fully shared across all resources. Thus, a job must be able to locate the necessary data and possibly transfer a copy to local storage. In large grids, data redundancy may be necessary to ensure timely access.

9. Security

The requirements for security cut across all aspects of a grid. User authentication must be reliable, data confidentiality must be respected, local resources protected, etc. With such broad requirements, security must be designed into grid software from the beginning and not put in place after the other aspects are designed.

The translation of these requirements into a working computational environment is an ongoing project that has not been fully developed. The Global Grid Forum (GGF) (Global Grid Forum, 2006) is an international body of vendors, developers, and users working to define a set of standards for interoperable grid software. It is an open forum with participants from all aspects of grid development, and most vendors with grid products are members of the GGF. The reference implementation of the GGF standards is the Globus Toolkit (Globus, 2006). Globus is designed as a layered architecture where core low-level services are used to construct high-level global services. This modular design allows a wide variety of applications to use the services necessary to meet their particular needs.

The Globus implementation has evolved with changing standards. Now, at version 4, its programming model is based on the Open Grid Services Architecture (OGSA). OGSA uses Web services to make resources available to grid users. The benefits of this approach include the following:

- Well-known open standards such as Simple Object Access Protocol (SOAP) and Extensible Markup Language (XML) can be used to define and access grid services.
- Additional services can be integrated into the existing infrastructure in a consistent fashion.
- New resources in the grid can be identified and utilized in a standard fashion.
- Interoperability between grids is possible based on standard toolkits and mutual trust.

The Open Grid Services Interface (OGSI) specification is the implementation of the OGSA standard. The OGSI defines the interfaces and protocols used between services in a grid environment. The transparent interoperability provided by OGSI does come at a cost in performance in the current implementation. Certain vital operations such as time-critical data transfer may require the use of other protocols to meet their performance goals until faster implementations emerge.

As the *de facto* standard, the Globus Toolkit has been used by most large public grids. The Biomedical Informatics Research Network (BIRN) (Biomedical Informatics Research Network, 2006) is a consortium of 30 research sites at 21 universities and hospitals. Set up to encourage collaboration among the research institutions, it has used Globus to share data collections and analysis tools. Similarly, the Open Science Grid (2006), the TeraGrid (2006), and the Enabling Grids for E-sciencE (EGEE) Project (Enabling Grids for E-sciencE, 2006) each bring together researchers across multiple disciplines to share resources. The EGEE Grid is possibly the largest, with over 30 000 CPUs and 5 Petabytes of storage available to the average of 10 000 jobs running at any given time.

It is important to note that the Globus Toolkit is in a turnkey package, but is a collection of components used to develop a grid in a specific environment. Smaller organizations may find the task of building a custom grid daunting and there are several packages available to create a departmental grid easily. The open source package Grid Engine, (2006) provides a complete package for building and running a compute or scavenging grid and can be installed as a turnkey system. When coupled with Grid Engine Portal, the end users are presented with a web portal allowing them to choose resources, submit and monitor jobs, and collect results. The web portal uses XML-based configuration files to create customized job submission pages for each grid application. Use of the web portal is not necessary in a Grid Engine environment and advanced users may find it easier to use command-line utilities, but the portal hides the command-line interface from the users who do not know or wish to use the underlying interface.

Despite the successes of the grids mentioned above, grid technologies are still in their infancy. Applications that migrate well to current grids are mostly limited to life sciences and physical sciences, and computation platforms generally use the

Unix or Linux operating system. To expand past the present base, more resources will be linked by more and better networks. The inclusion of lower-end devices (Personal Digital Assistants (PDAs), cell phones, sensor networks) will create grids of greater heterogeneity with large variations in the performance of individual components. The end result will be moving closer to the goals of autonomic computing and self-healing networks. Programming models will also change to take advantage of these resources, with interfaces developed to cope with resource discovery and selection. The end result can merge the incoming data flow from sensor networks or experimental instrumentation with the compute power of a large grid to produce real-time analysis of data on a scale not seen before.

Tutorial

Attacking performance bottlenecks

Ruud van der Pas
Sun Microsystems, Inc., Amersfoort, The Netherlands

1. Introduction

More than ever, application tuning is of paramount importance to reduce the time to process the data. This is increasingly the case in bioinformatics, as witnessed in the parallelization of NCBI BLAST (**http://mpiblast.lanl.gov/**).

Typically, the data sets have grown in size over time. In many cases, the algorithms used to process the data increase nonlinearly with respect to the execution time.

Meanwhile, a quiet revolution is taking place in microprocessor technology. Instead of focusing on improving the performance of a single, monolithic processor, attention has shifted to multicore technology.

With this technology, a single processor turns into a relatively small parallel computer. This is done at the expense of squeezing everything out of the single core performance. Typically, the clock speed increase is no longer as aggressive as it used to be. Caches are smaller, and there is a certain level of cache sharing too.

This paper is organized as follows. In Section 2, the recent hardware trends are presented and briefly discussed. In Sections 3, 4 and 5, the impact of this on the developer is discussed. Section 6 covers the importance of tools in this area. A summary of a selection of the tools Sun Microsystems has to offer is given in Section 7.

2. Technology – recent history

The performance of today's computers relies heavily on the use of fast buffer memory, called a *cache*. This has been the case for quite a number of years now.

Recently, the so-called *multicore* processor designs have emerged. This not only provides parallelism on the chip but it also adds another dimension to the structure of the cache subsystem.

In this section, these new concepts, to the extent relevant for application performance and developers, are briefly introduced and discussed.

2.1. Cache memories

The speed of the main memory system has not kept up with the increase in processor clock speed. Microprocessor technology follows Moore's law

(**http://www.intel.com/technology/silicon/mooreslaw/** The original paper can be downloaded from **ftp://download.intel.com/research/silicon/moorespaper.pdf**), which states that the number of transistors on a chip roughly doubles every 18 months. Although not automatically implied, for a long time this has translated to a proportional increase in the clock speed of the processor.

This law is however not applicable to the speed of main memory. The rate of increase is less, giving rise to an ever bigger performance bottleneck.

This discrepancy has existed for many years now and has been addressed by computer architects primarily with the use of cache memory. A cache is nothing more, or less, than a relatively small buffer memory, substantially faster than main memory.

Modern systems have a hierarchy of caches, logically placed between the CPU and main memory. The size and cache architecture details are system specific, but the rule is easy. The closer the cache is to the CPU (measured in terms of access time, not physical distance per se), the smaller it tends to be.

Caches are typically used to buffer three types of information needed to execute an application: data, instructions, and address mapping structures. The latter is generally referred to as the translation lookaside buffer (TLB) cache.

The number of caches, functionality, respective sizes, and internal architecture details are decided by the microprocessor design team. These choices are driven by technology, power requirements, target market(s), and time to market.

2.2. Multicore processor designs

Not long ago, microprocessors were only able to execute one single thread of execution at any point in time. Through context switching, it appeared as if the system was executing more than one task simultaneously, but this was not the case in reality.

With the advent of multicore designs, this scenario has changed.

Basically, this technological trend is driven by the increased complexity, power consumption, and heat dissipation of the conventional microprocessor designs. Caches only help to a limited extent, keeping the processor busy doing useful work. In particular, because of the widening memory gap, processors are increasingly burning more power doing nothing, waiting for the data to arrive.

The increased complexity of these designs magnifies this problem. For a number of years, highly specialized features have been added. Only a few applications benefit from these features, but meanwhile both the processor design time as well as the demand on power have gone up.

To counter this problem, multiple *cores* were placed on a single processor. Although the word “core” is not well defined, and vast differences exist between various designs, a fairly accurate way to view it is as a relatively simpler compute engine, capable of executing instructions, producing results, and having its own state information, like a program counter and registers.

The advantages of this multicore design are an impressive aggregate performance from a single processor, reduced or stationary power consumption, and a reduced time to market.

Now, all microprocessor vendors have realized these advantages. Either they are already shipping multicore designs, or will do so in the near future.

There is also a price to pay though. When it comes to performance, each core is relatively weak, compared to a traditional, but fully fledged, single monolithic design. Not only is the clock speed relatively lower, the caches are also smaller.

Some of these designs also use a combination of caches *shared* between the cores, together with caches that are private to the core.

For the purpose of this introductory paper, this aspect will be ignored. All that is relevant in as far as the memory system goes is the existence of one or more caches, each with potentially different sizes and access times, but always significantly faster than main memory.

3. Why can't I simply wait for faster processors?

Many do not consider tuning the performance of an application as an efficient investment of time, and therefore money. Simply waiting for faster processors to appear on the market is an easier and cheaper way to realize the performance level desired. (Of course, this does not hold for a relatively small category of power users who need to squeeze every single drop of performance out of the system.)

Even though the clock speed of processors has steadily increased and is well into the gigahertz range these days, fewer and fewer users have enjoyed a corresponding increase in performance when upgrading their system. The widening memory gap is a big contributor to this anomaly.

Given the multicore trend, one should no longer expect to see dramatic increases in the clock speed of the individual cores. These designs favor the overall workload by getting more work done in the same amount of time, but the performance of an individual application does not increase as dramatically as before.

The method to improve the performance of a single application is to exploit the parallelism inherent in these multicore designs (*"A Fundamental Turn Toward Concurrency in Software"*, Herb Sutter, **http://www.ddj.com**).

4. Five different ways to optimize an application

How does the application developer take into account all of the above-mentioned hardware performance features *and* become prepared for future developments in technology?

The answer is to leverage and use the possibilities listed in the following text, preferably in the order of appearance.

1. *Operating system features* Each operating system has a specific set of performance-oriented features that are worth exploring and, where applicable, using.

An operating system has many parameters and comes with several features that affect performance. These have to be set and chosen such that a wide range of applications and tools perform well enough, even under varying operational conditions.

These choices need not be optimal for a single program or a limited set of programs. Knowing the characteristics of a specific workload helps in identifying different settings and selecting special features that improve performance.

2. *Optimized libraries* Through the operating system and externally provided optimized libraries, the developer is not only able to leverage the tuning investment put in by others but is also automatically able to derive benefits from specific performance features in case the software executes on different hardware that runs the same underlying software layer.
3. *Compiler features* Today's compilers are powerful, but also complex, tools. A rich set of options is available to the user, but, just as with an operating system, the default settings have been chosen to get good performance across a wide variety of applications.

   If one knows the runtime behavior of the application, the use of specific additional options, or change in the settings of those already used, can make all the difference when it comes to performance. It is not uncommon to obtain a speedup of a factor of 5–10 when switching on the (right) optimization options on the compiler.

   In general, it is important to have a good understanding of what modern compilers are capable of. In some cases, developers are overly pessimistic, or optimistic, as to what a compiler can do when it comes to automatically restructuring the source code to improve performance.

   It is difficult to give general advice on this aspect. Some compilers are smarter and offer more features than others. It is a good investment in time to study the documentation that comes with the compiler.
4. *Source code changes* The effort spent on this can be unlimited, but we have found that quite often there is low hanging fruit in many applications.

   By addressing these, an impressive performance gain with a relatively modest investment can be achieved.

   To be honest, this need not always be the case, though. Some modifications can have a profound impact. If, for example, the way the data is organized in memory has to be changed, the definition and usage of the data structure(s) involved are affected throughout the application. The reward is usually not only high, but tends to also have a positive impact on other systems besides the target hardware.

   Finding the balance by writing efficient and readable code that can still be maintained is key. This is also related to a good understanding of the compiler one is using.

   What complicates the matter is that this is somewhat of a moving target as well. As time goes by, compiler technology improves. Some compilers implement an impressive set of transformations and optimizations. In particular, one should be careful while manually implementing low-level optimizations. These may not only jeopardize performance in a future release of the compiler, but could also backfire if used on a different platform.

5. *Parallelization* With parallelization, sometimes also referred to as *multithreading*, multiple processors (Nowadays, these could be cores too.) are used to execute a single application. By assigning different tasks to the processors, the turnaround time is reduced. Ideally, this decrease in execution time is proportional to the number of processors used, or phrased differently, if P processors are used, the program finishes in $1/P$ of the original time.
   This is the ultimate method to increase performance. The downside is that it could be a relatively time-consuming process to identify and implement the parallelism.
   To a certain extent, the effort needed to parallelize an application also depends on the programming model selected. The intrinsic parallelization potential within the application plays a role too. Some programs are easier to parallelize than others.

To wrap this up, it is important to realize that the preceding five steps are best addressed in the order they are presented.

The first two phases (operating system features and optimized libraries) are the lowest hanging fruit. Merely by taking advantage of certain features and optimization efforts put in by others, a significant performance increase is already realized at virtually no cost.

The third step (compiler features) requires some more work, but it does not go beyond reading the compiler documentation and possibly conducting some additional experiments with various options that affect performance. This could still be considered to be low hanging fruit.

Step four (source code changes) goes beyond that and should only be considered once the other three options have been explored in detail. How much effort is to be put into implementing source code changes to improve the performance depends on various factors, including the amount of time available for the task at hand.

The use of high-quality tools to guide this effort is highly recommended. Further information on this can be found in Section 6.

In view of the last step (parallelization), the main focus of these sequential, single thread, tuning efforts should be on the memory behavior of the application.

In particular, the caches should be used in the best possible way. In addition to the reduced execution time of the application, the parallel performance, as a function of the number of threads, also benefits from this kind of optimization. This is in particular true on a multicore processor, or shared memory system with a shared interconnect.

Because of increased use of the cache(s), the number of memory transactions is reduced. This in turn implies that there is less traffic per processor on the interconnect. Therefore, the available total bandwidth can be shared by more processors, or cores in case of a multicore design.

5. Five parallel programming models

In a way, there is no escape for those who need to squeeze the most out of a multicore design in order to reduce the turnaround time of a single application.

Parallelization is the way to accomplish this and those who start today have a head start. We will not make things any prettier than they are: parallelizing an application may be hard work. The reward is high however, and a careful choice of programming model and software development environment can greatly help to ease the task.

Many parallel programming paradigms are available, each with its own set of pros and cons. Some of these are very briefly summarized in this section. In Section 6 an overview of the recommended software environment is given.

1. *Automatic parallelization* To start with, certain compilers support automatic parallelization, or "autopar" for short. Although not a programming model in the strict sense, it is mentioned here, because it is worth exploring.
   Through a compiler option, the user requests the compiler to identify portions of the application that can be executed in parallel. If such occurrences are found, the compiler also generates the corresponding runtime infrastructure. Typically, this is in the form of calls to a multithreading library.
   The resulting binary that is generated this way can be used to execute on a shared memory and/or multicore system. It cannot be run on a cluster of systems that do not share memory.
   Success or failure of automatic parallelization depends on the programming language used, the application (area), the coding style, and the quality of the compiler, in particular, the dependence analysis component. The mileage will vary, but it is certainly recommended that this feature be tried, in case it is supported by the compiler at hand.
   The alternative approach is called *explicit parallelization*. In this case, the developer is fully in charge and decides what parts of the application are to be parallelized and how the parallelism is to be implemented. (On some systems both autopar and certain explicit parallel programming models can be combined.)
2. *POSIX threads* This powerful model for C and C++ supports parallelization within one address space. In other words, it is not possible to run an application parallelized with this model over different physical systems that do not share the memory.
   Through explicit insertion of function calls, the programmer implements and controls the parallelism.
   The advantage is that this threading model has been standardized. A disadvantage is that it is fairly low level: there are more details to worry about and the increase in the number of source lines is significant.
3. *Java threads* This model is similar to POSIX threads, but specific to the Java programming language. It essentially has the same pros and cons as POSIX threads.
4. *MPI, the message passing interface* There are specifications for C/C++ and Fortran in this programming model (**http://www-unix.mcs.anl.gov/mpi/standard.html**). The distributed memory model is supported: each process has exclusive access to private memory only. The other message passing interface (MPI) threads are not able to access it. (This is true even if multiple MPI processes are executed on a single shared memory system.) Information is exchanged and data shared by sending and receiving messages.

This model provides for great flexibility with respect to the execution environment. An application parallelized with MPI can be run on any cluster of computers that supports an MPI runtime environment.

The downside is that almost the entire burden is on the developer. All of the data exchange has to be put in by the programmer through the insertion of explicit, MPI- specific function calls to control the parallelism and exchange information by sending and receiving messages.

Moreover, care needs to be taken that the time spent in the communication part of the application is (significantly) less than the computational time. For example, it is often more favorable to combine several smaller messages into one large packet.

MPI is not an official standard, but the various implementations available adhere very well to the specifications. Therefore, portability is generally not an issue.

5. *OpenMP* The use of this shared memory programming model is on the rise. The specifications for C/C++/Fortran can be downloaded from (**http://www.openmp.org**).

   In contrast with the models discussed earlier, OpenMP provides a higher level interface. Through the so-called directives, the developer implements and controls the parallelism. In addition to this, runtime functions to query and change the execution environment are available. An example is the `omp_get_num_threads()` function call to change the number of threads used.

   In C/C++, a directive is a pragma with an OpenMP-specific syntax, for example, `#pragma omp parallel for` to parallelize a for-loop.

   In Fortran, directives use a specific language comment string, such as `!$omp parallel do` to parallelize a do-loop.

   This approach ensures portability, as a non-OpenMP compiler simply ignores the pragmas or comments, whereas an OpenMP compiler triggers on the keywords and translates these into the appropriate parallel infrastructure, typically calls to a lower-level parallelization library.

   OpenMP has several advantages over other programming models. The application can be parallelized incrementally. This also allows for incremental testing.

   Another useful feature is that the OpenMP application can be written such that the sequential version is preserved. This is convenient in case a bug is revealed. By not compiling specific parts of the source for OpenMP, the directives are ignored and deactivated/activated. This not only speeds up finding the root cause of the problem, but it can also be used as a workaround if time to market is important and troubleshooting is not feasible before releasing the application.

   Last, but not least, OpenMP compilers can assist the user too. By issuing warning messages, for example, the compiler may point the developer to a possible error. This is much harder, if not impossible, to do in other explicit parallel programming models.

The choice of programming model depends on several important factors. It is therefore hard to give recommendations, but we think that the OpenMP

programming model offers several attractive features justifying a serious look into it as a model of choice.

Thanks to the multicore trend, hardware availability is increasingly less of an issue. In the not too distant future, all new computers will be equipped with these kinds of processors, turning the system into a shared memory parallel computer. This is even true for laptops.

The programming benefits that OpenMP offers make it suitable for the beginner as well as for the more advanced developer.

6. The importance of application development tools

Without the right tools, it is very hard to develop an efficiently performing application. (Of course, correctness is always an issue; in case parallelism is considered, this is extra hard.)

At the tools level, application tuning starts with the compiler. A good compiler takes advantage of the features the hardware offers. Exploiting the cache hierarchy is a case in point, but there are many other optimizations an advanced compiler can perform. Ideally, this can be achieved with a minimal effort by the user.

This is the starting point only though. Application tuning has to be a guided effort, focusing on those parts where the application spends most of the time.

A performance analysis tool is extremely useful to identify such hot spots.

An important aspect to consider is the level of detail the tool provides. Knowing only the most expensive function(s) is usually not sufficient. Especially if the function is complicated, source line level performance information is needed to identify the time-consuming parts within the function. In some cases, there is even a need to drill deeper and find the most expensive instruction(s).

Modern microprocessors offer hardware performance counters that give low-level information on the various activities within the processor.

With this feature, one can, for example, measure how often the application accesses the cache(s) and the number of times the data requested is in the cache(s). The ratio of these two numbers is called the *cache hit rate* and is an indicator of how well behaved the application is from the point of view of a cache memory. In addition to cache-related activities, other events too can be measured.

Although hardware counters are useful, it is not always easy to access them and gather the data. A tool to assist the user with this is a must have for those interested in performance tuning.

Parallel processing adds another dimension to performance analysis. In this case, it is important to know how the various processors perform relative to each other. For example, are they all marching along in an efficient and synchronized way, or does one processor need more time than the others? In case of the latter, the parallel performance is most likely not optimal.

A tool to identify these kinds of bottlenecks is invaluable to improve the efficiency of a parallel application.

Last, but not least, ensuring correct execution of a parallel program is nontrivial.

In case of an MPI application, for example, the exchange of messages might be incorrect, giving rise to wrong results. Another source of errors is a missing, or

incorrect, synchronization operation. These and other errors are bugs causing the parallel application to produce wrong results or hang.

What makes it extra hard is that some of these problems only manifest themselves on a specific processor configuration. They could even be dependent on the actual load on the system and interconnect.

Troubleshooting these types of errors requires a debugger specifically developed for MPI applications. Examples are TotalView (**http://www.etnus.com**) and DDT (**http://www.allinea.com**), but these are not the only MPI debuggers on the market.

The shared memory programming model comes with its own set of possible bugs. A so-called data race is one of the most difficult errors to find.

Simply stated, with a data race, the update of a shared variable is not well protected, for example, when different processors simultaneously update the same shared variable with a different value.

This gives rise to unpredictable results. The variable could basically take any value, depending on the number of processors used and the order in which the write operations to memory are issued.

The behavior of a parallel application that has a data race bug is unpredictable. Even if the same number of processors are used, the error may or may not appear. Therefore, extensive testing may not reveal a data race and a tool to detect these is of great importance when developing a shared memory parallel application.

7. Tools by Sun Microsystems

In this section, we briefly discuss some of the Sun Microsystems software products that are available to assist the user in developing an application for multicore processors.

The Solaris Operating System (**http://www.sun.com/software/solaris**) offers many performance-related features that are worth exploring. For example, the DTrace tool that is part of Solaris 10 is very helpful to diagnose and analyze performance bottlenecks at the system level in particular.

The Sun HPC Clustertools product provides an efficient implementation of the MPI-2 specification (**http://www.sun.com/products-n-solutions/hardware/docs/Software/Sun_HPC_ClusterTools_Software**).

The Sun Studio Compilers and Tools (**http://developers.sun.com/prodtech/cc**) suite offers a comprehensive set of tools to assist the developer with the development and optimization of sequential as well as shared memory parallel applications.

The Sun compilers implement state-of-the-art optimizations, support automatic parallelization, and implement the most recent, 2.5, OpenMP specification.

The compilers have extensive support for OpenMP. Runtime performance optimizations and debugging features, as well as options to assist the user during the development cycle are provided.

An Integrated Development Environment (IDE) is part of Sun Studio as well. With that a debugger, editors, and so on, are available. It also includes the Sun Studio Performance Analyzer (**http://docs.sun.com/app/docs/doc/819-3687**), a performance analysis tool for applications written in C, C++, Fortran or Java. At

the parallel programming level, POSIX threads, Solaris threads, Java threads, MPI, automatic parallelization, and OpenMP are supported.

This analyzer presents performance information at the function, source line, and instruction level. Easy access to hardware event counters is also supported.

The Sun Studio Thread Analyzer is a tool that helps in finding data race conditions in a shared memory parallel application. It is available for download as part of the Sun Studio Express program (**http://developers.sun.com/prodtech/cc/downloads/express.jsp**).

8. Conclusions

With the advent of multicore processors, the developer is faced with two challenges. The single core performance will no longer improve as dramatically as it has done in the past. Secondly, parallelization is the way to exploit the computational power these architectures offer.

The OpenMP programming model in particular is very suitable for taking advantage of multicore designs.

Good tools are an absolute must when it comes to developing or adapting applications to this new paradigm.

Glossary Terms

Glossary compiled by Clare E. Sansom

School of Crystallography, Birkbeck College, London, UK and freelance bioinformatics consultant and science writer

Accessibility The amount by which an amino acid within a protein structure is exposed on the surface of the protein and thus exposed to the polar solvent. Numerical values for accessibility can be used in protein structure prediction; polar and charged amino acids most often have high accessibility values.

Accession Number A number (most often an alphanumeric) that is assigned to an data entity – for example, a gene or protein sequence – when it is added to a database. The accession number is one of the primary keys for database searching. Each database uses a different series of accession numbers. Cross references to accession numbers are used to link between databases.

Adenovirus A DNA virus with a core made of DNA/protein and a capsid composed of 252 capsomers. The double-stranded DNA genome is about 36-kb long and contains inverted terminal repeats at its ends. Adenoviruses are often used as vectors in gene therapy. They have many advantages for this, among them that it is possible to delete large parts of the viral genome without destroying viral function.

Aequorin A bioluminescent protein that is used in functional proteomics as a sensitive assay for calcium and that does not disrupt cell function. A blue light is produced when calcium ions bind to a complex of aequorin protein with molecular oxygen and coelenterazine. Aequorin was originally obtained from the jellyfish Aequorea victoria, but a recombinant form is now available.

AI *See* Artificial Intelligence

Algorithm A mathematical method of data analysis that is (usually) progammed into a computer and that can be proven to produce the solution desired. Examples in bioinformatics include the Smith–Waterman and Needleman–Wunsch algorithms for sequence alignment. There is often more than one possible algorithm to produce a given solution; fast and elegant solutions are preferred.

Algorithm, greedy *See* Greedy Algorithm

Alignment An arrangement of two or more protein or nucleic acid sequences to maximize the number of matches and, with protein sequences, the number of near matches. Alignment algorithms are some of the most important and commonly

used in sequence analysis. A number of more or less rigorous algorithms for local and global alignment are widely available.

Alignment, Gapped *See* Gapped Alignment

Alignment, Global *See* Global Alignment

Alignment, Local *See* Local Alignment

Alignment, multiple *See* Multiple Alignment

Allele One of two or more differing forms of a gene occupying the same locus on the same chromosome. An allele may differ from all other alleles of that particular gene at one or more mutation sites; each gene may have up to 1000 different potential sites of mutation. If the only mutations are silent (leading to no change in the amino acid), the phenotypes of two or more alleles may be the same.
Source: Kahl, G, The Dictionary of Gene Technology (Wiley-VCH, 2001).

Allelomorph *See* Allele

Alpha Bundle A group of alpha helices clustered together to form a stable unit within a protein structure. An alpha bundle may form all or part of a protein domain.

Alpha Helix One of the two main types of secondary structure found in proteins. An alpha helix is a tightly coiled protein conformation with 3.6 residues per helical turn and a rise of 1.5 Angstroms per residue. The carbonyl group of residue "n" in the helix is hydrogen bonded to the amino group of residue "$n+4$". Alpha helices are extremely stable and are found in almost all proteins.

Alternative Splicing The ligation of exons from a gene to form a different mRNA, and thence a protein with a different sequence (and potentially a different structure and/or function) from the conventional one. Some exons may be left out of the mRNA, or the exons may be spliced in a nonconventional order. This is one of the mechanisms for increasing the number of protein products from a genome of a given size, and it is more common in higher organisms.

Amphipathic A molecule is defined as amphipathic or amphiphilic if it has one face that is much more hydrophobic than the other. Amphipathic helices are present both on the surfaces of soluble proteins, with the hydrophobic face pointing into the protein centre, and in transmembrane helix bundles, with the hydrophobic face pointing "out" toward the membrane phosopholipids. This feature can be used to predict helix locations and orientations.

Amphiphilic *See* Amphipathic

a.m.u., Dalton *See* Atomic Mass Unit

Analog Proteins that have evolved separately to perform similar functions, through the process of convergent evolution, are known as analogs. The folds of protein analogs may, but will not necessarily, be similar. The alpha/beta barrel (TIM barrel) proteins, which are all enzymes, are examples of protein analogs with similar folds; the serine proteases trypsin and subtilisin have closer functions but completely different folds. It is much harder to model a protein structure from an analog than from a known homolog.

Anaphase In the cell cycle, the phase between metaphase and telophase during which the daughter chromosomes are drawn toward either end of the dividing cell by the microtubules that are attached to the chromosome centromeres. Chromosome separation errors during both meiosis and mitosis are often picked up at this stage, blocking further cell division. However, these errors may not be detected during meiosis in the female, so most human trisomies result from nondisjunction errors arising in the egg cell.

Aneuploid A polyploid cell is defined as aneuploid if its chromosome number is not an exact multiple of the haploid number, caused by an error in mitosis: an aneuploid individual is one with a countable number of aneuploid cells. Individuals suffering from trisomies, most commonly trisomy 21, are aneuploid. The normal state is known as euploidy.

Annealing In the polymerase chain reaction (PCR) and similar technologies, the word annealing is used to mean the initial attachment of a complementary oliogonucleotide primer to a DNA or RNA sequence prior to the start of the reaction. It is not to be confused with the molecular dynamics technique of simulated annealing, used, for example, in ab initio protein structure prediction.

Annotation The process of determining the features encoded by a genome sequence, and marking the genome sequence with those features in order. Genome annotations include the function of encoded genes, the position of introns in eukaryotic genes, recognized regulatory sequences, and statistical measures such as CG content. One example of a widely used annotation tool is Artemis, which is freely available and widely used for prokaryotic and simple eukaryotic genomes.

Antibody An important part of the mammalian immune system; a serum protein that is secreted by plasma cells after contact with a foreign molecule (antigen). Antibody-antigen binding is a signal to other components of the immune system that the antigen is a foreign substance. Potentially toxic proteins are precipitated and removed from solution, whereas bacteria are agglutinated. There are several varieties of antibody, composed of differing numbers and arrangements of immunoglobulin domains; the most common is the IgG, with four such domains.

Antigen Any molecule, or part of a molecule, that is recognized and bound by an antibody (immunoglobulin) as part of the mammalian immune response. Antigens may be small organic molecules or loops on the surface of proteins. Identification of

potential antigenic regions in proteins is a useful bioinformatics exercise in vaccine design.

Apoptosis In short, apoptosis is programmed cell death, and it is common in multicellular organisms. In apoptosis, cells die in a controlled, regulated fashion, in response to a complex series of stimuli. Thus, the cells play an active part in their own death (which is why apoptosis is sometimes referred to as cell suicide). Unlike necrosis, it is an essential part of the development of all organisms.

Archaea A third class of organisms, distinct from both the bacteria and the eukaryotes, originally distinguished from the bacteria by an analysis of the evolution of rRNA structure. Archaea are now thought to be the first ancestors of eukaryotes. They are, however, prokaryotes, as they are single-celled organisms with no nucleus. Extremophiles, which thrive in "extreme" conditions such as high temperature or high salinity, are archaea.

Artificial Intelligence A type of algorithm that depends on modeling tasks and processes that are normally associated with the need for human intelligence. It usually involves encoding facts from an area of human knowledge into a complex set of rules and applying these to a problem. Artificial intelligence algorithms were particularly popular in some areas of bioinformatics during the 1970s and 1980s. They are less popular today, but they are still occasionally used.

Association Mapping An approach to genetic mapping involving the testing for functional polymorphisms or mutations using genetic markers that are in linkage disequilibrium (LD) with the mutation under test. Investigations typically compare sets of cases and controls, although other methodologies are available. Association mapping is more sensitive than straightforward linkage mapping in detecting small and moderate genetic effects involved in common, multigenic disorders. It is not yet possible at the whole-genome level.

Association Study A type of study in medical genetics in which the association of given genetic patterns (i.e., SNP markers for particular genes) with given phenotypes, most often diseases, is studied. If the marker is found significantly more frequently in the cases than in the controls, it indicates an association between the disease or trait and the marker (and therefore the gene) under study.

Atomic Mass Unit A unit of mass that is used to measure atomic and molecular masses, defined as 1/12 of the mass of one atom of the isotope Carbon-12. It is (approximately) equal to $1.66053886 \times 10-27$ kg. In biochemistry and molecular biology, the term "dalton" is most often used as a synonym. However, atomic mass unit (or a.m.u.) is used to refer to masses, and errors in masses, of peptide ions measured by mass spectrometry in proteomics experiments.

Autosome The autosomes are those chromosomes that do not determine the sex of an individual: for example, chromosomes 1-22 of the human genome are

autosomes. Traits that are determined by genes on the autosomes are inherited in an autosomal fashion; they are not sex specific.

Autozygosity Mapping A mapping strategy for identifying the loci and identity of genes involved in autosomal recessive (simple Mendelian) diseases. The allele studied is not only homozygous but identical by descent; it is often used with consanguineous families. The technique was discovered in theory in the 1950s but not exploited until the late 1980s.

BAC A 6.5 kb bacterial cloning vector, based on a single-copy F-factor of *E. coli*, that allows the cloning of DNA fragments of greater than 300 kb (although by no means all cloned fragments are of this size). The BAC is composed of the *E. coli* plasmid pMBO 131, carrying a chloramphenicol resistance gene, HindIII an BamH1 cloning sites, sites for rare cutters and a bacteriophage lambda cos N and lox P site.
Source: Kahl, G, The Dictionary of Gene Technology.

Backcross A type of genetics experiment in which a hybrid individual animal is crossed with one of its (typically inbred) parents, or an animal bred through such an experiment. The mouse is by far the animal that has been most widely studied in this way; laboratories such as the Jackson Lab hold panels of DNA samples from mouse backcrosses.

Bacterial Artificial Chromosome *See* BAC

Bacteriophage *See* Phage

Balancing Selection *See* Heterozygote Advantage

Basic Local Alignment Search Tool *See* BLAST

Beta Propeller A fairly common type of all-beta protein fold, found in, for example, the influenza virus surface protein, neuraminidase. A large number of beta strands are arranged into a number (generally 4–6) of consecutive motifs, each made up of four short antiparallel beta strands. These form the "blades" of the propeller and are arranged in a circular structure, with the active or binding site in the center.

Beta Sheet One of the two main types of secondary structure found in proteins. A beta sheet consists of two or, much more often, more extended beta strands, held together through a network of main chain–main chain hydrogen bonds between adjacent strands. Adjacent strands may be parallel or antiparallel, and the hydrogen bonding patterns between the different types are different. Whole sheets may be parallel, antiparallel, or mixed. At least one sheet is found in the majority of proteins.

Beta Trefoil A type of all-beta protein fold, found in, for example, cytokines, lectins and agglutinin. It contains a closed beta barrel and a hairpin triplet, and has

internal threefold symmetry. The beta trefoil fold is defined as Architecture 2.80 in the CATH database, and it has only one Topology sublevel (2.80.10 Trefoil).

Biallelic A mutation, or a marker, is described as biallelic if the gene involved has only two different forms. Single nucleotide polymorphisms are generally biallelic, in that only two amino acids are commonly formed at the SNP position. In contrast, microsatellites and other tandem repeats are not biallelic because they may have many different lengths.

Bilayer A double layer. Most often used to describe the double layer of phospholipids that makes up the membrane surrounding all cells and organelles. The hydrophilic head groups and parallel hydrophobic tails of the phospholipids in a membrane bilayer strongly affect the amino acid composition of proteins associated with membranes.

Binominal A binominal distribution is a statistical distribution derived from many different trials, each of which may have only two possible outcomes – for example, the toss of a coin, which may only result in a "head" or a "tail". The distribution of the numbers of "heads" that may possibly be obtained from x tosses of a coin is a binominal one.

Bioconductor An open source and open development software project to produce code for bioinformatics, and particularly for the analysis of genomic data. There is a strong focus on microarray analysis, although other topics are also addressed. The public domain statistical package R, which is also often used for microarray analysis, is a prerequisite for the development of Bioconductor software.

Bioluminescence The emission of photons of visible light by a living organism (generally a lower one, although some species of fish produce bioluminescence). It is usually generated by the oxidation of a substrate. The luciferase bioluminescence system, found in nature in the firefly *Photinus pyralis*, is often used as a marker for transient gene expression or genetic transformation.
Source: Kahl, G, The Dictionary of Gene Technology.

BioPerl An international association of software developers of open source bioinformatics programs and tools using the Perl language. It provides a set of free on-line resources, tutorials, and libraries of Perl scripts for developers to use. It is facilitated by the Open Bioinformatics Foundation, and has links with other open source software developers including BioPython, BioJava, and EMBOSS.

BioPython An international association of software developers of open source bioinformatics programs and tools using the Python scripting language. It provides a set of free on-line resources, tutorials, and libraries of Python scripts for developers to use. It is facilitated by the Open Bioinformatics Foundation and has links with other open source software developers including BioPerl, BioJava, and EMBOSS.

Biosynthetic Pathway *See* Metabolic Pathway

BLAST A very popular and very fast bioinformatics tool for searching a gene or protein sequence database with a single sequence. The test sequence is aligned with each database sequence in turn, using a crude, rapid algorithm that is based on initial identification of short exact matches, and the best matches are reported. There are many variants of BLAST, including the iterative PSI-BLAST which is only available for protein sequences.

Block In bioinformatics theory, a block is an alignment of a section of (usually protein) sequences where there is a high degree of identity between the amino acids in the block. Each protein family is represented by a number of blocks, and this family information is held in the BLOCKS database. The empirical data in this database was used to derive the popular BLOSUM family of amino acid substitution matrices.

BLOSUM Matrices A series of amino acid substitution matrices generated empirically using the protein sequence alignments in the Blocks database. The numbers reflect the number of substitutions observed in the Blocks alignments. There is a series of matrices defined using different Blocks; for example, the popular BLOSUM62 matrix is derived from only those blocks that have 62% or higher sequence identity. The BLOSUM matrices are now more popular than the classic PAM matrices, although the latter are still used.

Boolean Logic The simple and ubiquitous logic in which states are combined using NOT, AND, and OR relations (sometimes combined into NAND and NOR). Boolean logic underlies the whole computer revolution, but in bioinformatics it is most obviously used in the more sophisticated type of database search. SRS is an example of a well-known bioinformatics software product that allows users to perform searches using complex Boolean logic.

Candidate Gene Approach A strategy used in the identification of genes that are linked with disease (particularly the many genetic risk factors for complex diseases). In it, one or more likely genes (the candidate genes) are first identified and the effects of polymorphisms of these genes are tested in an association study. It is possible to use this approach to identify genes that are weakly linked with disease. However, it has one key disadvantage: the disease must be understood well enough for suitable candidate genes to be identified.

Capillary Electrophoresis A technique to separate ionized molecules in silica capillaries with a diameter of 25–100 μm and a length of 20–100 cm by electro-osmotic flow. It combines the advantages of effective heat dissipation with reduced sample volume. The detection limit may be extended to sub-attomolar concentrations of the ions using high-sensitivity detectors such as laser-induced fluorescence detectors. Capillary array electrophoresis uses an array of 96 or 384 capillaries filled with polyacrylamide gel.
Source: Kahl, G, The Dictionary of Gene Technology.

Capsid The DNA or RNA genomes of all viruses are surrounded by protein coats known as capsids. Some also have a lipid bilayer membrane enclosing the

capsid. The capsids of simple spherical viruses are roughly spherical shells made up of many copies of each of a small number of subunits. These subunits are generally assembled into the capsid with icosahedral (=20-fold) symmetry; the smallest capsids are composed of 60 identical subunits.

CCD *See* Charge Coupled Device

cDNA A single- or double-stranded DNA molecule that is complementary to an RNA (usually mRNA) template from which it has been copied by RNA-dependent DNA polymerase (reverse transcriptase). Complementary DNAs immobilized onto "chips" and able to hybridize to mRNAs present in a cell sample are the basis of microarray technology.
Source: Kahl, G, A Dictionary of Gene Technology (Wiley-VCH, 2001).

cDNA array, DNA chip, gene chip *See* Microarray

cDNA Clone Set A set of DNA duplexes complementary to mRNA molecules, generated by the reverse transcription of the mRNA messages using reverse transcriptase and cloned into a plasmid or other cloning vector. Clone sets from eukaryotic genomes may be very large, and many have now been made freely available for recognized not-for-profit researchers.
Source: Kahl, G, The Dictionary of Gene Technology.

Centromere That part of a eukaryotic chromosome (as it is visible under the light microscope during metaphase and with the morphology generally associated with the word "chromosome") at which the two chromosome copies are held together. The centromere separates the p and q arms of the chromosome. Very few genes are found in the centromeric regions of chromosomes.

Chaperone Proteins that help other proteins to fold are known as chaperones (or molecular chaperones). They are found in the proteomes of all organisms except viruses, but have been studied in most detail in *E. coli*. The *E. coli* proteome contains two distinct families of chaperones, the Hsp70 chaperones and the chaperonins (exemplified by the GroEL/GroES complex). Chaperonins do not define other proteins' folds, but enable them to find their correct structures. Different chaperonin families have different mechanisms.

Charge Coupled Device A light-sensitive integrated circuit that stores data from an image, pixel by pixel, in such a way that the charge intensity stored is related to the color of the image. CCDs have many uses, but, in proteomics, they can be linked to signals from fluorescent proteins, converting the light signals to electric charge.

Chemical Shift The key measurement in NMR spectroscopy: that is, the difference between the observed resonance energy of a nucleus (of non-integral spin, e.g., 1H, 13C or 15N) and the standard value expected for that nucleus.

This difference can be correlated with the chemical environment of the nucleus concerned, and thus used to deduce structural details of that part of the molecule.

Chemiluminescence The emission of visible light as a consequence of the excitation of atoms or molecules by absorption of free energy from a chemical reaction. Metastable energy-rich intermediates are created, and these emit visible light as they decompose into their ground states. Chemoluminescence detection is a sensitive method for detecting specific proteins or DNA molecules using an enzyme-linked probe.
Source: Kahn, G, The Dictionary of Gene Technology.

Chemotaxis The directed movement of a microbe, or a motile cell, following a chemical concentration gradient. Positive chemotaxis is movement toward a higher chemical concentration, negative chemotaxis movement toward a lower one. Many proteins have been identified as being involved in mediating or responding to chemotaxis through activation of intracellular signaling pathways or remodeling of the cytoskeleton through the activation or inhibition of actin-binding proteins.

Chimerism The word chimera (chimaera) is used to mean both an organism composed of two or more genetically different cell types, and a DNA construct composed of sequences with different origins. Similarly, a chimeric gene (fused gene) is a genetic construct comprising coding seqences from one gene expressed under the transcriptional control of another.

Chromatin Chromatin is the name given to the complex of DNA and proteins that makes up eukaryotic chromosomes. In these, DNA is associated with DNA-binding proteins called histones. During the 1970s, both nuclease protection experiments and electron microscopy proved that histones are spaced regularly along the DNA, like beads on a string. Each bead is termed a nucleosome. The compact DNA-protein complex around the periphery of nondividing nuclei is termed heterochromatin.

Chromosomal Rearrangement Simply, the rearrangement of chromosomal parts, leading to chromosomes that contain parts of others. Chromosomal rearrangement is common in many genetic diseases and in cancers. Some cancers are associated with characteristic chromosomal rearrangements; one example is chronic myeloid leukemia, which is almost always associated with a translocation of part of chromosome 22 onto chromosome 9.

Chromosome Banding Chromosomes may be stained to produce the characteristic binding patterns that are illustrated in a karyogram and used to identify them by number. For example, the common G-banding procedure, involving mild proteolysis followed by staining with the Giesma stain, will produce dark bands where the DNA is AT-rich and light bands where it is GC-rich.

Chromosome substitution strain, CSS *See* Consomic Strain

CID *See* Collision-induced Dissociation

Cis-Element Cluster A cluster of sequence elements cis of (that is, in the 5′ untranslated region of) a gene. Many of these DNA sequences bind regulatory factors and are therefore involved in the regulation of gene transcription; they include, for example, TATA boxes and Ets sequences. Cis-element clusters can be detected from sequence patterns using programs such as Cister, and their presence is used in gene-finding algorithms as signals of functional genes.

Cis-splicing The joining (splicing) of two exons from the same pre-mRNA, with the removing of the intervening intron sequence. This self-evidently occurs only in eukaryotes, since prokaryotic genes contain no introns. Exons and introns are partly defined by splice site sequences, but there is not a strong enough consensus in these for them to be sufficient. Proteins are involved in splice site identification in the context of cis-splicing, and these also influence alternative splicing events.

Clade In phylogenetics, any subtree growing from a single node, whether it is a single sequence or taxon or a large group, is termed a clade. Thus, the vertebrates, the mammals, and the genus Homo may all be described as clades. There is always one common ancestor that organisms in a clade share with each other but not with others in the phylogenetic tree.

Clonality A clonal population – that is, one displaying clonality – is a population (of cells or of bacteria) that is derived from a single cell. Thus, a population of cancer cells derived from a single mutant cell will be clonal. In microbial genetics, a population of bacteria displays clonality if it has evolved without recombination; there may, however, be significant sequence diversity derived from mutation.

Cluster of Orthologous Groups *See* COG

Clustering A mathematical technique in which points in large data are "clustered" into groups depending on their properties. In bioinformatics, clustering is often used to analyse microarray datasets and group genes with similar expression profiles. Clustering algorithms used in microarray analysis include hierarchical clustering, self-organizing maps (SOMs), k-means clustering, and principal component analysis.

Codon A triplet of bases that codes for a particular amino acid or for a START or STOP signal. Four bases give a total of 4ˆ3 or 64 different possible codons, so with 20 coded amino acids there is significant redundancy. In the standard genetic code, some amino acids (e.g., Trp) are coded by only one codon, others (e.g., Leu) by as many as six.

Coevolution A reciprocal evolutionary change in two or more species that interact together, or, a change in the genetic composition of one species as a result of a genetic change in another that interacts with it. The term is usually attributed

to Ehrlich and Raven (1964) who studied genetic diversity in butterflies and their host plants in relation to the interactions between them.

Co-evolution *See* Coevolution

Coexpression The simultaneous transcription of two or more different genes, and the translation of the resulting mRNAs in a cell. Coexpression of different transgenes may be achieved by fusing them to a specific type of promoter, or by placing two different promoters in opposite orientation between the genes.
Source: Kahl, G, The Dictionary of Gene Technology.

Cofactor If an enzyme requires another molecule to take part in the reaction that it catalyzes, and if that molecule is not changed by the reaction, the molecule is termed a co-factor for that reaction. Co-factors are usually fairly small organic molecules, and nucleotides and nucleotide phosphates are common ones. The co-factor generally binds to a different site on the enzyme from the substrate.

COG A third class of organisms, distinct from both the bacteria and the eukaryotes, originally distinguished from the bacteria by an analysis of the evolution of rRNA structure. Archaea are now thought to be the first ancestors of eukaryotes. They are, however, prokaryotes, as they are single-celled organisms with no nucleus. Extremophiles, which thrive in "extreme" conditions such as high temperature or high salinity, are archaea.

Coiled Coil A protein structure composed of two or three parallel alpha helices packed or wound together (coiled round each other); such a structure is more stable than straight helices lying side by side. They are often found in fibrous proteins. The helices display a pattern of hydrophobic and hydrophilic residues that repeats every seven residues, and several bioinformatics programs have been written to predict coiled coils from sequence using these rules.

Coimmunoprecipitation A purification procedure that is used to determine whether two proteins interact. An antibody to one protein is added to a cell lysis. The antibody-protein complex then is pelleted, usually using protein-G sepharose (which most antibodies will bind to). Proteins that bind to the first one will also be pelleted, and can therefore be identified either by Western blotting or by protein sequencing.

Co-IP *See* Coimmunoprecipitation

Collision-induced Dissociation A technique used for determining the sequences of proteins or peptides using mass spectrometry. In it, the mass-charge ratio of selected ions is first determined and then those ions are further fragmented through collisions with (usually) noble gas atoms. The sequence of the original fragment can be determined from the mass-charge ratios of the ions generated from the second set of collisions.

Compartment, Subcellular *See* Subcellular Compartment

Complementary DNA, copy DNA *See* cDNA

Complex Disease *See* Multigenic Disease

Concept Disambiguation The process by which, in order to provide the interpretation or definition of a complex term (e.g., when constructing an ontology) the different concepts within the term are disambiguated, that is, the particular sense of the term in the appropriate context is determined. (One simple example of a term that has different meanings in different contexts is the noun "virus", which has different meanings in microbiology and in computer science.)

Conformational Sampling Any method of modeling the likely conformations of a molecular structure (e.g., a protein or protein–ligand complex) that involves taking a random sample of conformations and calculating their energy. Systematic sampling is only possible if the molecules are fairly small. Monte Carlo analysis is a good example of a nonsystematic conformational sampling technique.

Congenic Strain A congenic strain of an experimental animal (most typically a mouse) is one that is genetically identical to the original, or host, strain at all positions except those linked to the gene of interest. It is obtained by a series of backcrosses between the host strain and a strain carrying the mutation of interest, usually with a mixed genetic background.

Consensus The dictionary definition of "consensus" is just "a general or widespread opinion" (Collins English Dictionary, 1986). The term has several specific meanings in bioinformatics. A consensus method of, for example, secondary structure prediction is a method in which the same prediction is made using several different algorithms and the result recorded only where there is general agreement. A consensus sequence is a sequence giving only those residues conserved in a multiple sequence alignment, with no residue recorded in the nonconserved positions.

Conservative Substitution A substitution of one amino acid for another that does not cause a significant change in the protein's function (hence conservative) and that is commonly seen in alignments of homologous sequences. Usually, the chemical nature of the amino acid pairs involved in conservative substitutions is similar. Phenylalanine for tyrosine (or vice versa) and leucine for isoleucine or valine are examples of conservative substitutions.

Consomic Strain A consomic strain of an experimental animal (most typically a mouse) is one in which a single chromosome from one inbred strain (the donor strain) is transferred onto the background of another strain (the host strain) by repeated backcrossing. It usually takes about 10 backcrosses to create such a strain. It is possible to create a panel of consomic strains using the same donor and host strains but with a different chromosome replaced in each one.

Constitutive Gene *See* Housekeeping Gene

Construct Simply, an informal (possibly “laboratory slang”) term for any recombinant DNA molecule: that is, any DNA molecule formed in vitro through the ligation of two or more nonhomologous DNA molecules. For example, a recombinant plasmid containing one or more inserts of cloned foreign DNA. The term may be derived from “in vitro constructed DNA”.
Source: Kaul, G, The Dictionary of Gene Technology.

Contig An abbreviation for contiguous segment; one of many genomic clones produced during a genome sequencing project that contains mutually overlapping DNA sequences. Obtaining contig sequences is now relatively straightforward: the latter stages of the genome project, called finishing, when the contigs are assembled in the correct order and joined to form the completed sequences, are the most time consuming.

Control Element A DNA sequence, such as a promoter or operator, that responds to an external signal (e.g., light, temperature) or an internal one (e.g., the presence of a hormone or other chemical signal) and so controls whether or not the gene associated with the control element is expressed. Transposons (transposable elements or mobile elements) in plants such as corn may also be termed control elements.
Source: Kahl, G, The Dictionary of Gene Technology.

Controlling Element *See* Control Element

Convergence In mathematics and computer science, an iterative algorithm is said to have converged (reached convergence) when the result is no longer changed from one iteration to the next. One example in bioinformatics is the iterative protein search program PSI-BLAST; this is said to have converged when a database search cycle adds no more protein sequences to the proposed list of matches.

Convergent Evolution If the same solution (in terms of protein structure and/or function) is arrived at two or more times during evolution, giving rise to two or more similar solutions with no direct evolutionary link between them, that is termed convergent evolution. Examples include the serine proteases trypsin and subtilisin, which have the same mechanisms but completely different structures, and the various families of unrelated enzymes with the TIM barrel fold.

Copy Number The number of a particular plasmid in a cell, or the number of a particular gene (or chromosome) in a genome. A low copy or “low cop” mutation is a mutation that leads to a decrease in the copy number of plasmids in a cell; it is not favored in recombinant DNA experiments. If there are only a few copies of a plasmid in a cell, that plasmid is termed a low copy number plasmid or stringent plasmid.
Source: Kahl, G, The Dictionary of Gene Technology.

Cosegregation The transmission of two or more genes on the same chromosome to the same individual in the next generation as a result of them having been included in the same gamete. The closer two genes are on a chromosome, the more likely they are to cosegregate. The opposite process, in which genes on the same chromosome are separated in the gametes, is recombination.

Cosmid A small extra chromosome found in bacteria, into which fragments of about 40 kb of DNA from various external sources may be introduced using recombinant DNA methods. This allows the foreign DNA to be replicated every time the bacteria divide; it is a common and useful technique in genome sequencing. This was one of the first methods to be developed for amplifying DNA in sequencing projects.

Co-transcription Two (or more) genes are cotranscribed if they are transcribed together into the same mRNA, and, usually, then translated together into protein. Genes that are cotranscribed must be linked and are almost always contiguous on the chromosome. Cotranscription and cotranslation gives rise to the presence of equimolar concentrations of proteins in the cell.

Covalent The atoms in organic molecules are connected by strong covalent bonds (single, double, partial double, or triple). Unlike noncovalent bonds, such as hydrogen bonds, they are extremely strong and can only be broken in chemical reactions. In molecular mechanics simulations, bond lengths are modeled using simple Newtonian mechanics, using parameters for bond length and strength that vary according to atom type and bond order.

Coverage The number of times, on average, that any piece of DNA has been sequenced in a genome sequencing project. As it is still only possible to sequence DNA in fairly small segments, each segment must be sequenced many times to make sure that the fragments will be assembled in the correct order. In general, the higher the copy number, the more accurate the assembled sequence will be.

Cryptic Relatedness A problem (or complication) in medical genetics, particularly in case–control studies, arising from correlation between alleles in a subpopulation that must be taken as independent. In case–control studies, where it is assumed that there is no genetic link between individuals, the "cases" must be assumed to be more likely to be related than the "controls" because they share a deleterious gene or genes.

2D-PAGE A technique for separating complex mixtures of proteins according to isoelectric point and mass, which has revolutionized the discipline of proteomics. The protein mixture is usually subjected to electrofocusing to separate by pI; the resulting 1D gel is separated by mass using SDS-PAGE.
Source: Kahl, G, Dictionary of Gene Technology, Wiley 2001.

Data Structure Trivially, a complete and self-consistent structure that can be imposed on a set of data, such as the elements of a database. Data structures have

been described as one of two core components of computer science, the other being algorithms. Ontologies and markup languages schemas are two types of data structure. Sequence and structure file formats (such as, respectively, the FASTA and PDB formats) can be thought of as specialized data structures.

Degeneracy Generally, any code that uses a "many to one" mapping, so that more than one term in the original map onto a single term in the code, is termed degenerate. Therefore, the genetic code is an example of a degenerate code: 64 different three-base codons map onto 20 amino acids plus the START and STOP codons, so more than one codon usually code for the same amino acid. The maximum number of codons that code for any one amino acid is six; the minimum number is one.

Deletant *See* Deletion Mutant

Deletion Mutant A mutant that has been generated by the loss of one or more base pairs from the DNA of its genome. Similarly, a deletion mutation is any mutation that results in base pair loss. If the deletion mutation occurs in a coding region, and unless the number of base pairs deleted is a multiple of three, a deletion mutation will cause a frame shift leading to a truncated gene and probably to a loss of gene function.

Dendrimer A highly branched multilayered DNA scaffold structure for the annealing of multiple oligonucleotide probes. A dendrimeric unit consists of a central double-stranded region with four single-stranded arms, which are complementary to the single-stranded arms of another unit. DNA dendrimer technology is useful for the detection of rare DNA or RNA sequences.
Source: Kahl, G, A Dictionary of Gene Technology.

Desolvation The process of breaking interactions between the atoms of (usually) a protein molecule and the molecules of the solvent in which the protein is dissolved, in order for the protein to fold. Generally, the interactions between protein and solvent atoms are stronger than those between atoms within the protein, so the process of desolvation requires energy. Desolvating hydrophobic atoms and groups is more energetically favorable than desolvating hydrophilic ones; desolvating polar atoms removes ordered hydrogen-bonding interactions from the solvent surrounding the protein and so increases the entropy of the system.

Difference Gel Electrophoresis *See* DIGE

Differential Expression Genes are not expressed equally in all cells and tissues; which of the potentially active genes are expressed in a given cell at a given time depends on the cell type, developmental stage, and even on whether or not the cell is diseased. Microarrays are used to determine differential expression – that is, differences in expression patterns – between genes in different cell types or under different conditions. This has important implications for differential diagnosis and for the selection of potential targets for drug design.

Differentially Methylated Region Regions of DNA in eukaryotic chromosomes that are methylated differentially on the maternal and paternal alleles are termed differentially methylated regions. Many of them are CpG islands. They are divided into two classes, one methylated during gametogenesis and the other methylated after fertilization. It has been suggested that methylation is the epigenetic mark (imprint) that differentiates the paternal and maternal alleles.

DIGE An emerging technique in proteomics where the protein samples are labeled with fluorescent dyes prior to separation using a 2D-PAGE gel. This enables up to three different images of the same gel to be captured (using the wavelengths of the different dyes) and differences between the images determined using image analysis software. The main advantage of this technique is the avoidance of gel-to-gel fluctuations: the main disadvantage is cost.

Dihedral Angle The torsion or twist angle that defines the geometric position of atoms separated by two other atoms in a covalently bonded chain: thus, if four atoms A–B–C–D are connected together, the dihedral angle is the twist angle about the B–C bond that defines the position of D with respect to A. Free rotation is only allowable about single covalent bonds. The dihedral angles that describe the structure of amino acids within proteins are named using Greek letters: the backbone torsion angles as phi, psi, and omega and the side chain angles as chi1, chi2 etc.

Diploid A eukaryotic cell is described as diploid if it contains a full copy of chromosome pairs. Thus, a human diploid cell contains two copies of each of the 22 autosomes and two sex chromosomes (XX for females and XY for males) making 46 chromosomes in all. All normal human cells other than gametes are diploid: these cells are also termed somatic cells.

Directed Graph In graph theory, a graph is defined as directed if its edges have direction (so that they join one node "to" another rather than joining them together). A graph describing relationships between genes will be directed if the relationship defining the edges is, for example, "regulates". Many applications of graph theory to bioinformatics use directed graphs.

Directon A contiguous series of genes on a (normally bacterial) chromosome, such that all the genes in the directon are transcribed in the same direction. Directons are easily identified and counted once the complete genome sequence is known. One directon may contain one, or more than one, operons (defined as transcription units containing two or more genes).

Discriminant Function A method of distinguishing between data based on the measurement of a set of properties. For example, in gene prediction, a method of distinguishing between genic and intergenic DNA based on patterns and frequencies of the different bases (e.g., GC content) would be described as a discriminant function. Although this is the most obvious one, the phrase can be used in other contexts in bioinformatics.

Distance, Evolutionary *See* Evolutionary Distance

Distance Matrix A matrix holding data on the evolutionary distance between amino acids (i.e., the probability that a substitution of one amino acid by another will be accepted). The most widely used examples are the BLOSUM series and the older, but classic PAM series. They are used in all protein–protein sequence alignments and database searches. The equivalent matrix in DNA sequence analysis is usally the identity matrix.

Disulphide Bond A contiguous series of genes on a (normally bacterial) chromosome, such that all the genes in the directon are transcribed in the same direction. Directons are easily identified and counted once the complete genome sequence is known. One directon may contain one or more than one operons (defined as transcription units containing two or more genes).

Disulphide Bridge *See* Disulphide Bond

Divergent Evolution The usual process of evolution in which DNA molecules diverge in sequence (and, thence, the protein products of the genes they code for may (or may not) diverge in structure and/or function can be described as divergent as opposed to convergent evolution. Divergent evolution may take place within or between genomes.

DMR *See* Differentially Methylated Region

DNA dendrimer *See* Dendrimer

DNA Methylation The enzymatic transfer of methyl groups onto nucleotides in DNA molecules, more precisely from *S*-adenosyl methionine onto C5 of cytosine residues (generally in eukaryotes) or N6 of adenine residues (generally in prokaryotes). Methyltransferases in prokaryotes are part of a restriction modification system: in eukaryotes, methylation of bases in the promoter region of genes can modulate gene transcription.
Source: Kahl, G, The Dictionary of Gene Technology.

DNA Polymerase Enzymes that catalyze the polymerization of deoxyribosenucleotide triphosphates into the DNA polymer based on the sequence template of a single-stranded DNA molecule. Polymerization proceeds in the 5′-3′ direction. DNA polymerases are used for DNA repair as well as replication. All organisms, apart from some viruses, contain one or more DNA polymerases. Some DNA polymerases also possess exonuclease activity, and some have important uses in molecular biology.

DNA Transfection; Transformation-Infection *See* Transfection

Docking A technique used in protein bioinformatics and especially in drug design, where a small organic molecule (e.g., a putative substrate or inhibitor)

is placed within the binding site of a protein and its geometry and position varied to minimize the energy of the system. (The term is derived by analogy with a ship docking in a port.) Many commercial and public domain automatic docking programs are now available.

Domain Most often used to describe part of a protein chain that will fold (and may be crystallized) independently. However, domains are also distinguishable by both function (e.g., a serine protease domain, a tyrosine kinase domain) and by sequence. The domain is the basic unit in both databases of protein structure (e.g., SCOP, CATH) and of protein sequence/function (e.g., Interpro).

Domain Chaining A phenomenon in protein function prediction that may lead to errors in domain identification. If protein X contains domains A and B, a sequence search will pick up similarity to protein Y containing domains B and C. If protein Z, containing domains C and D, is also identified – wrongly – as having similarities to X, domain chaining has occurred. Careless use of the iterative search program PSI-BLAST may lead to domain chaining.

Domain Recombination The process through which multidomain proteins with different structures and functions can be generated by combining domains in different numbers and orders. A large proportion of proteins contain more than one domain, and a relatively small number of domains (compact units with similar 3D structures and, generally, similar functions) are found in a wide variety of multidomain proteins. Domain recombination is much less common in integral membrane proteins.

Domain Swapping A mechanism for forming oligomeric proteins from their monomers, in which one domain of a multidomain, monomeric protein is replaced in the protein 3D structure by the same domain from an identical protein chain. The resulting intertwined dimeric or oligomeric structure is extremely stable. Large domains, supersecondary structures and single helices or strands may be involved in domain swapping. In one example, some cysteine proteases crystallize as domain swapped dimers.

Dominant In Mendelian genetics, a phenotype is defined as dominant if it is displayed in an individual that is heterozygous for the characteristic (containing one allele with the gene for the trait and the other without). Thus the normal phenotype is dominant in cystic fibrosis (recessive inheritance), but the disease phenotype is dominant in Huntington's disease (so all individuals who inherit the HD allele will develop the condition if they live long enough; dominant inheritance). The term incomplete dominance is used when the heterozygous phenotype is intermediate between the two homozygous ones, and codominance where both homozygous phenotypes are observed to some extent in heterozygote.

Dominant Negative Mutation A mutation that, when expressed in a heterozygote, produces a gene product that interferes with the functioning of the normal

gene product is termed a dominant negative mutation. The mutant protein usually combines physically with the normal one to form a dimer. In these cases, heterozygotes invariably exhibit a disease phenotype (which may or may not be the same as that of homozygotes for the mutant gene) and the inheritance will be described as dominant, codominant, or incomplete dominant. The allele involved is an antimorphic allele.

Dot Matrix A method of comparing two sequences (or whole genomes) as a simple plot of one sequence against the other, by sliding a window along each sequence in turn. If the two segments under consideration are similar enough, a dot is drawn at the specified point on the plot; lengths of sequence similarity are therefore represented by diagonal lines. The degree of similarity between the sequence segments required for a dot to be drawn is termed the stringency of the plot.

Dot Plot *See* Dot Matrix

Downstream Toward the 3′ end of a DNA sequence. The term is most often used for sequence that is located 3′ of the coding sequence of a gene. The 3′-most region of that sequence that is transcribed into the pre-mRNA (but not translated into protein) is known as the 3′-untranslated region (3′-UTR). The region downstream of the 3′UTR, which is never transcribed into mRNA, may also be of interest.

Drug Target A protein that is involved in a disease state and where it is thought that chemical intervention (most often, but not always, using a small organic drug molecule) may alter that activity and affect the progress of the disease. Out of tens of thousands of proteins in the human and pathogen proteomes, only about 400 had been used as drug targets by the turn of the twenty-first century. Proteins that are thought to be good drug targets are (self-evidently) frequently selected by (e.g.) structural proteomics programs.

Dyad The word dyad is used in general terms to describe a pair, so some people may refer to, for example, a hydrogen bond donor – acceptor dyad or a protein – ligand dyad. However, in DNA sequence analysis, the word has a specific meaning: it is used to describe a sequence fragment that is immediately followed by its reverse complement. Statistical analysis has been used to determine whether dyads are distributed evenly within chromosomes or genomes.

Dynamic Programming A programmming technique that involves breaking the problem down into constituent subproblems, which may share some components (sub-subproblems) and storing ("memorizing") the results of the shared components. In bioinformatics, dynamic programming is used in, for example, the Needleman–Wunsch and Smith–Waterman alignment algorithms. In these, the use of dynamic programming allows for the computationally efficient incorporation of gaps.

Dynamic Range The range of, for example, protein concentrations that may be detected by a given technique, expressed in orders of magnitude. Commonly used

silver staining techniques, for example, may detect protein concentrations over a range of only two orders of magnitude, whereas the newer fluorescent techniques may have a range of up to five orders of magnitude. A technique is said to have a linear dynamic range if the relationship between a signal and the respective concentration is one of simple proportion (so plotting signal against concentration gives a straight line).

Dysmorphology Dysmorphology is the study of abnormal form in humans, and, therefore, of genetic disorders that cause external malformations, whether simple or complex, mild (often hardly visible) or severe enough to cause disability. Many such abnormalities are caused by the malfunction of developmental genes. Large numbers of familial dysmorphology syndromes, inherited in the Mendelian pattern, are known, and the mapping of these has led to the development of molecular dysmorphology and to the mapping of developmental genes.

Edge In graph theory, objects, known as nodes, are connected by lines indicating relationship; these are known as edges. The edges may or may not have directionality, depending on the relationship modeled, and they be labelled to represent different degrees of relationship. Graph theory has many applications in bioinformatics, where is used to cluster the most closely related objects (typically genes or proteins) together. Edges may represent, for example, relationships such as "is coexpressed by" (for genes) or "interacts with" (for proteins).

Electrophoresis In theory, the movement of charged molecules in solution within an electric field. In practice, any method for separating charged molecules that uses an electric field, exploiting differences in the charge, shape, and size of the particles. The core proteomics technology of two-dimensional gel electrophoresis involves the separation of particles in two dimensions, according to both charge and size.
Source: Kahl, G, The Dictionary of Gene Technology.

Electroporation A method for the direct transfer of macromolecules, most often DNA, into cells by perforating the cell membrane with a short electric pulse and a potential gradient, leading to a transient permeabilization of the cell membrane. The process will allow the entry of large DNA molecules that may be integrated into a nuclear or organelle genome.
Source: Kahl, G, The Dictionary of Gene Technology.

Electrospray Ionization A technique used in protein mass spectroscopy, as applied to the analysis and identification of separated proteins obtained in proteomics experiments (e.g., 2DPAGE). A solution of the digested peptides is passed through a thin needle with a nebulizing gas, and a high voltage applied to the tip. This generates a spray of droplets containing ions. The droplets evaporate leaving peptide ions which pass through a series of electrodes and samplers to the mass analyzer, which usually works on the time-of-flight principle.

Electrotransformation *See* Electroporation

Embryonic Stem Cells A type of nondifferentiated cell that is derived from a very early embryo and has the potential to differentiate into any one of many different types of cell. Embryonic stem cells have enormous potential in medicine, but their use has important ethical implications, is extremely controversial, and has been banned in many countries. Rather less controversial technologies involving ES cells include the production of transgenic mice by incorporating genes containing mutations into mouse ES cells to produce lines of transgenic mice.

Endogenous Retrovirus A complete retrovirus sequence that is integrated into a recipient genome. ERV sequences may be complete, containing the full gene complement of exogenous retroviruses, or incomplete. The human genome contains several ERV families (known as HERVs). These are transcribed but not normally translated, and all human endogenous retroviruses are noninfectious.
Source: Kahl, G, The Dictionary of Gene Technology.

Endosome A vesicle, derived from the cell membrane, through which cells absorb material (such as nutrients) from the environment in a process known as endocytosis. Typically, the cell membrane forms a pocket containing the nutrient, which pinches off to form a vesicle that ruptures to release its contents into the cytoplasm. It is the opposite of exocytosis, the process through which waste products and toxins are excreted from the cell.

Endosymbiosis The evolutionary theory that states that organelles within eukaryotic cells must have evolved from prokaryotes that were engulfed by the primitive eukaryotes. Specifically, mitochondria are believed to have evolved from aerobic bacteria (probably related to the rickettsias) living within the host cells, and chlorplasts are believed to have evolved from endosymbiotic cyanobacteria (autotrophic prokaryotes). This theory explains the fact that organelles have their own genomes.

Energy Minimization The technique in which the geometry of a molecular system is altered in order to minimize its energy. Most energy minimization programs work with a molecular mechanics model of the molecule, which defines it in terms of its geometry (bond lengths, angles, and torsion angles), atom types, and partial atomic charges. There are many problems with this methodology, not least the likelihood that the molecule will simply move into the nearest local minimum conformation rather than the global energy minimum. However, it has its uses in the final stages of homology modeling and in estimating interaction energies of molecular complexes.

Epigenetic Factor Any factor that affects gene expression without altering the sequence of the genes involved. Some epigenetic factors, such as DNA methylation, involve permanent, covalent bonds to the DNA molecules; others involve the structure of molecules such as chromatin that interact with the DNA via nonbonded interactions. If chromatin is particularly dense, transcription factors may be physically prevented from reaching the DNA, preventing transcription.

Epigenetics The altering of gene expression by any means that is not related to the sequence of bases along the DNA molecule. Epigenetic modifications of DNA, such as DNA methylation, changes in chromatin structure and histone deacetylation affect the expression of many genes and are involved in diseases such as cancer. Epigenetics also goes part way to explain differences, for example in complex disease incidence, between identical twins (who, of course, have identical DNA sequences).

Ergodic Theory A mathematical theory related to the theory behind Markov modeling, which has many applications in bioinformatics (e.g., gene finding and protein function prediction) and that also has applications in thermodynamics. It is a statistical theory saying, in simple terms, that if all states of a system are equally accessible, they will be occupied with equal probability if sampled over a long period of time.

ERV *See* Endogenous Retrovirus

ES Cells *See* Embryonic Stem Cells

ESI *See* Electrospray Ionization

EST *See* Expressed Sequence Tag

Eutherian A Eutherian mammal is a member of the subclass Eutheria of the class Mammalia: that is, any mammal with a placenta (the structure in the uterus of a pregnant female that allows the transport of nutrients to, and waste products from, the developing fetus). The only mammals that are not Eutherian are the marsupials and the monotremes.

E-value A statistical measure of the similarity between two sequences, related to the probability of the sequences being unrelated (thus, the lower the E-value, the more significant the match). The E-value, or expect value, is a measure of the number of unrelated sequences in a database the size of the one used that would be expected to be at least as similar to the test sequence as the one chosen.

Evolutionary Distance A measure of the closeness of the relationship between the genomes of two organisms (generally two species) measured from the amount of divergence between aligned homologous regions of DNA. Evolutionary distance is most commonly measured using the number of nucleotide substitutions per site, although this method is not always the most useful for reconstructing phylogenetic trees. One well-known example is the evolutionary distance between mouse and rat, which can be given as 0.014 indels per site.

Evolutionary Dynamics The study of the dynamics (forces on and changes in over time) of populations undergoing evolution – that is, of populations capable of mutation and subject to selective pressure. Evolutionary dynamics may be applied at the molecular or organism/ecosystem level.

Evolution, Convergent *See* Convergent Evolution

Evolution, divergent *See* Divergent Evolution

Exon Those sequences within a eukaryotic gene that are conserved during pre-mRNA processing and so make up the mature message (c.f. Intron). The introns on the 5′ and 3′ ends of the mRNA may contain sequences that signal initiation or termination of processing, respectively, and so are not translated into protein. Prokaryotic genes do not contain introns, so the concept of exons is meaningless there.

Exon–intron Structure The structure of a eukaryotic gene, in terms of the number, order and size of the coding exons and the noncoding exons that separate them. Eukaryotic genes vary widely in exon–intron structure, from single exon genes, through genes with a simple structure such as insulin with its single intron, to genes where over 90% of the genetic material consists of introns. It is even possible for one gene to be embedded in an intron of another gene.

Exon Skipping The elimination of one or more exons from a transcript during splicing, such that the combination of exons remaining results in a different mRNA and hence in a translated protein with a different arrangement of domains. For example, a gene with three exons, A, B, and C may give rise to a protein containing domains coded from only exons A and C as a result of the skipping of exon B.
Source: Kahl, G, The Dictionary of Gene Technology.

Expect Value, Expectation Value *See* E-value

Expert System A form of artificial intelligence in which the knowledge associated with an area of human expertise is codified into a set of rules that are then applied to the analysis and classification of data. Like artificial intelligence, more generally, expert systems are less common in bioinformatics than they were 20 or 30 years ago. They do, however, have some applications there, and they are more common in clinical applications.

Expressed Sequence Tag A short, synthetic oligonucleotide of 300–500 bp, complementary to the 5′ or 3′ end of a specific mRNA and usually derived from a cDNA library by random sequencing. ESTs represent tags for the state of gene expression in a given cell type at a given time (disease status and/or developmental stage). Millions of sequenced ESTs have been deposited in public databases: ESTs represent the largest subdivision of the EMBL and GenBank databases.
Source: Kahn, G, The Dictionary of Gene Technology (Wiley-VCH, 2001).

Expression Cartridge *See* Expression Cassette

Expression Cassette A DNA fragment (usually synthetic) into which foreign DNA can be cloned and expressed. The expression cassette is usually part of an expression vector and encodes a control region (e.g., promoter) with an

adjacent Shine–Dalgarno sequence (for expression in prokaryotes), a signal peptide sequence if necessary, a polylinker, and a termination sequence.
Source: Kahl, G, The Dictionary of Gene Technology.

Expression Profile The simultaneously measured levels of many thousands of mRNAs (expressed genes) in a cell or tissue type, detected using a microarray. The classic microarray experiment measures differences between the expression profiles of different cell types, or the same type under different conditions.

Expression vector; expression cloning vector; transcription vector *See* Vector

External Spike-in Control A standard pool of cDNA sequences showing no sequence identity to the human genome (or the other genome under analysis) used as controls in microarray experiments. The samples, which span a large concentration range, are added to the RNA samples before labeling and can be used to test for efficiency of cDNA synthesis/labeling, uniformity of hybridization, and sensitivity of detection.

FASTA A bioinformatics tool for searching a gene or protein sequence database with a single sequence. FASTA is complementary to BLAST; it is slightly more precise, but runs much more slowly. The database is scanned for those sequences that contain the largest number of perfect matches to short subsequences of the test sequence, and each of these best matches is then aligned more precisely. FASTA has also given its name to the most commonly used sequence file format, where the sequence title is given on the first line preceded by a greater-than sign.

FID *See* Free Induction Decay

Fingerprint A pattern of peptides obtained from a protein by proteolytic degradation (very often using the protease trypsin) and then separated and identified using mass spectrometry and optionally peptide sequencing. The peptide fingerprint produced by a particular protease is characteristic for each protein and can be used for protein identification.

FISH A technique used to study the details of an individual's chromosomes, and particularly to determine chromosomal abnormalities either before or after birth. It involves labeling segments of single-stranded DNA (known as probes) with fluorescent dye. If the cells of the individual under study contain chromosomal DNA that is complementary to the probes, they will bind and the fluorescent signal will be detected. Unlike most techniques for chromosomal analysis, it does not need to be performed on dividing cells.

Fluorescence In Situ Hybridization *See* FISH

Fluorescence Resonance Energy Transfer A technique used in many proteomics applications, for example, in probing the structure of proteins, and protein–protein and protein–ligand interactions. It uses the fact that energy can,

under certain circumstances, be transferred between two dye molecules (donor and acceptor) in close proximity without the emission of a photon. The absorption spectrum of the acceptor must overlap the fluorescence emission spectrum of the donor and the dipoles of the two molecules must be approximately parallel. It can be used to determine intermolecular distances of the order of tens of Angstroms.

Fluorophore Any molecule that produces fluorescence and that can therefore be used as a probe, typically in proteomics experiments. In proteomics, fluorescence may be described as intrinsic or extrinsic. Intrinsic fluorophores may be fluorescent molecules that are naturally bound to the protein, perhaps as cofactors, or amino acids with intrinsic fluorescence. Green fluorescent protein contains the unusual intrinsic fluorophore of a STG tripeptide, which is posttranslationally modified to a 4-(p-hydroxybenzylidene)-imidazolidin-5-one. Extrinsic fluorphores are fluorescent molecules that may be artificially bonded to proteins.

Fold The level in protein structure classification that groups together proteins with the same secondary structure elements connected in the same order. The FOLD level in the SCOP database equates to the Topology level in CATH. Proteins with the same fold may have a common evolutionary origin, but homology cannot be assumed, particularly with the highly populated so-called superfolds (examples being the alpha-beta barrel and the immunoglobulin fold).

Fold Prediction A method for predicting the tertiary (three-dimensional) structure of a protein that does not necessarily require the structure of a homologous protein to be available. It involves aligning the sequence of the protein to be modeled with known protein structures and using “threading” or a similar algorithm to select structures that are most compatible to the test sequence. It is a low precision method and cannot be used to predict novel folds, but it has had some notable successes, particularly in selecting remotely homologous structures as templates for homologous modeling.

Force Field A self-consistent representation of a molecule or molecular system (e.g., protein, ligand, and solvent molecules) using Newtonian mechanics, which can be used for energy minimization or molecular dynamics simulations. Atoms are represented by points with size, mass, and partial atomic charge, and bonds as “springs” separating them. Bond lengths, bond angles, and torsion (twist) angles are maintained close to optimum positions using energy terms, and other energy terms define the nonbonded forces between atoms. Given the crudity of this model, it can produce some surprisingly good results, but these techniques must be used with caution.

Founder Population The small population that first invades an isolated area such as an island. Descendents of a founder population will exhibit reduced genetic variation as a result of this population bottleneck. Human communities that descended from founder populations may exhibit unusually high prevalence of Mendelian diseases.

Fourier Transform A mathematical transform that expresses a function as a sum or integral of sinusoidal functions multiplied by constants known as amplitudes. There are many distinct forms of Fourier transforms, which were named for French mathematician Jean Baptiste Fourier. The most common applications of Fourier transforms in areas related to molecular biology are in structural biology, in deconvoluting X-ray and electron diffraction patterns to obtain the structures of macromolecules.

Fourier Transform Ion Coupled Resonance A mass spectrometry method that is able to measure masses of, for example, peptide ions, with very high precision and accuracy. It is a versatile analysis method that may be used with both MALDI and ESI ionization technologies. It is an ion-trapping method, based on the principles of ion cyclotron resonance (ICR) spectrometry; one of its few disadvantages is that it is very sensitive to pressure and requires near vacuum conditions.

Frameshift An alteration of the reading frame of a gene in which the sequence is read (i.e., translated into protein), caused by a change in sequence length (i.e., an insertion or deletion) of a number of nucleotides that is not divisible by 3. It usually results in the production of a truncated, nonfunctional amino acid because all the sequence downstream of the change will be translated incorrectly.

Free Induction Decay In structure determination by NMR, free induction decay (FID) is a transient signal that decays (or relaxes) exponentially with time and that is caused by dephasing in an inhomogeneous magnetic field. The signal is sinusoidal and it is generated by spins in the $x-y$ plane; it decays over time as magnetization returns to its equilibrium level.

FRET *See* Fluorescence Resonance Energy Transfer

FTICR *See* Fourier Transform Ion Coupled Resonance

Gain of Function Mutation Trivially, any mutation where the protein produced by the mutated gene displays extra functionality (either a different function altogether or an enhancement in normal function) that is not present in the wild type. Gain of function mutations may be beneficial or deleterious; inheritance of these mutations is usually, if not always, dominant.

Gapped Alignment Any alignment of two or more sequences that includes gaps, that is, that allows for insertions and deletions in the sequences. In practice, almost all alignment methodologies in modern bioinformatics produce gapped alignments; the only nongapped alignments are local alignments used where speed is at a premium. Early versions of BLAST produced nongapped alignments.

Gap Penalty A penalty that is deducted from an alignment score for the addition of a gap in a sequence alignment. Alignment programs generally use two different gap scores: a large penalty for starting a gap (the gap insertion penalty) and a smaller penalty for extending one (the gap extension penalty). This reflects the fact

that there is a greater difference between an ungapped alignment and one with an insertion or deletion of a single character (base or amino acid) than there is between an alignment with a single insertion or deletion and one with two.

Gene Duplication An event during evolution in which a single gene is duplicated, giving rise to two different genes in the same genome. These genes will gradually diverge on an evolutionary timescale, giving rise to gene products with different sequences and usually different, although related, functions. Genes in the same genome that are related in this way are known as paralogs.

Gene Fusion The use of recombinant DNA techniques to join (fuse) together two or more genes coding for different products so that they are expressed under the control of the same regulatory system.
Source: Kahl, G, The Dictionary of Gene Technology (Second Edition).

Gene Gun A piece of apparatus used for inserting transgenes into plant cells. Genes are loaded on to very small gold or tungsten pellets. These are then fired at the leaves or other tissues of the target plant, using the gene gun. The pellets pass through the plant tissue, but the genes are physically wiped off the pellets and may be incorporated into the plant chromosomes.

Gene Index A list of genes; specifically, an annotated, nonredundant list of the genes in a genome, generally including other related genetic information and links. The TIGR Human Gene Index, which is freely available, contains data on the expression patterns, functions, and evolutionary relationships of the genes in the index. Gene indexes for other, less well studied genomes will tend to be less complete.

Gene Knockout An informal term used in the lab and less frequently in non-specialist publications for the disruption of a gene by the addition or deletion of base sequences so that the function of the gene is abolished. Knockout mice, or mice in which the function of one gene has been removed, have very important uses in the study of genetic diseases.

Gene Silencing The inactivation of a previously active (i.e., previously transcribed) gene. Its converse, gene activation, is used to mean the activation of a previously silent gene. Silencing (or activation) may take place by altering the transcription mechanism of the gene rather than the sequence of its coding regions.

Genetic Anticipation A phenomenon in which some genetic diseases are observed to appear in more severe forms, either in terms of symptom severity, age of onset, or both, in subsequent generations. Genetic anticipation is common, and has been widely studied, in the trinucleotide repeat disorders (e.g., Huntington's disease) but it has also been observed in some more common complex diseases with a strong genetic component, including Crohn's Disease and biolar disorder.

Genetic Drift A random change in the frequencies of different alleles in a population that is neither deleterious nor beneficial. The term is also used to mean

random change as a mechanism of evolution; it is believed to be one of the two most important such mechanisms, with natural selection. Moran, in the reference below, states that random genetic drift is by definition a stochastic mechanism.

Genetic Imprinting An epigenetic process by which the male and female germline of viviparous species confer specific marks on certain chromosomal regions, leading to the activation of either the paternal or the maternal allele only in somatic cells. Imprinted regions are characterized by increased and specific DNA methylation at particular CpG nucleotides. About 100–200 genes are believed to be imprinted in mammals, including man.
Source: Kahl, G, The Dictionary of Gene Technology.

Genetic Profile Simply, a profile of the variation in one or many genes in an individual or population. In medical genetics, the genetic profile of an individual may be used to predict their likely susceptibilty to disease; in evolution, and particularly in microbial evolution, the genetic profile of a population may be used to track its changes over time or space.

Gene Transfer The main mechanism through which genetic material is transferred between species of bacteria. Bacteria are unable to reproduce sexually, so horizontal gene transfer is the only mechanism other than mutation through which variation is introduced into bacteria. The main methods are the uptake of "naked" DNA from one DNA species into the chromosome of the other, the transfer of plasmids or transposons, and the transfer of DNA using phages.

Gene Trap A method of creating large numbers of insertional mutants in the mouse genome, which is both high throughput and cost-effective. A gene trap vector is inserted at random into the genome of mouse embryonic stem cells, simultaneously disrupting the gene at the site of the insertion. A reporter gene is used to monitor the expression of the inserted gene. The resulting databases of mutant stem cell lines may be used to establish mutant strains of mice via the creation of chimaeras.

Genomic Control A method of reducing the chance of finding spurious associations between genes and disease in the large populations that are necessary for the study of the genetics of complex diseases, caused by population heterogeneity. By studying multiple polymorphisms scattered through the genome, many of which are known not to be associated with the disease in question, it is possible to estimate population heterogeneity and take it into account.

Genomic Imprinting *See* Genetic Imprinting, Imprinting

Genomic Orphan, ORFan *See* Orphan Gene

Genotype The genetic composition of an individual (of any species), as opposed to the physical features imposed by that genotype (the phenotype). The term may be used either to describe the alleles that are present at a particular locus or

to describe the organism's overall genetic composition. Thus, to take a simple case, the genotype of a cystic fibrosis carrier at the CF locus is different from that of an unaffected individual, although their phenotypes are (in that aspect) indistinguishable.

Germ Cell A eukaryotic cell that has been produced by meiosis and that is therefore haploid (containing only one copy of each chromosome). Germ cells are egg cells in the female and sperm cells in the male. Most other types of eukaryotic cell cannot pass information to the next generation and are known as somatic cells.

Germline All cells in an individual that contain genetic material that can be passed on to that person's children are part of the germline. Self-evidently, this includes the egg and sperm cells, but it also includes the cells from which those cells are derived – the gametocytes. If a mutation occurs in a germline cell (a germline mutation), that change may be passed on to future generations.

GFP *See* Green Fluorescent Protein

Gibbs Sampling An algorithm for finding patterns (corresponding to, e.g., structural properties or functional motifs) within a set of DNA or protein sequences. One sequence is left out of the set; the other sequences are aligned and the alignment used to produce a scoring matrix. This is matched to the extra sequence and used to predict the pattern; a second sequence is then left out of the resulting complete alignment and the procedure repeated until the matrix can no longer be improved.

Global Alignment Any sequence alignment technique in which the assumption is made that the (gene or protein) sequences are homologous along their entire lengths. Gaps are inserted into one or both sequences in an attempt to stretch the alignment to cover all the sequences. This method is appropriate for, for example, aligning orthologs from different genomes: it is not appropriate for aligning whole genes with partial ones or cDNA with genomic DNA.

Global Free Energy Minimum The conformation of a molecule (or molecular complex) that has the lowest free energy, as measured (generally) using a molecular mechanics force field. The global minimum is distinct from a large number of local energy minima in different parts of conformational space. Molecular mechanics calculations make the assumption that a molecule or system is most likely to be found in its global minimum, and the difficulty of distinguishing this from the local minima is one of the drawbacks of this methodology.

Global Minimum *See* Global Free Energy Minimum

Glycoconjugate A generic term used to describe any macromolecule that consists of an oligo- or polysaccharide (i.e., a glycan) covalently bound, or conjugated, to another type of molecule. Glycoproteins and glycolipids are examples of glycoconjugates.

Glycomics The study of the glycome of a cell or organism. By analogy with genomics and proteomics, the glycome is defined as the complete set of simple and complex carbohydrates that it makes. The glycome, like the proteome, is many times more complex than the genome.

Glycoprotein A glycoprotein is a protein that is glycosylated – that is, one in which one or (more often) more asparagine, serine, or threonine side chains have been covalently linked to sugar moeities. Glycosylation is a posttranslational modification.

Glycosidic Linkage The covalent link between the protein and carbohydrate parts of a glycoprotein or proteoglycan. There are two main types of such linkages: N-glycosidic linkages, where the oligosaccharide is attached to the amide nitrogen of an asparagine residue, and O-glycosylation, where the oligosaccharide is linked via the side chain hydroxyl group of a serine or threonine residue.

Glycosylation Island A locus on a eukaryotic chromosome that contains genes that code for proteins involved in glycosylation. The genes are close enough together for the locus to be defined as an operon.

Glycosylphosphatidylinositol Anchor One of the three main groups of post-translational glycosylation modifications of protein sequences, the others being O-glycosylation and N-glycosylation. Proteins with GPI anchors are attached to the cell membrane by means of the anchors; they are found in all eukaryotic genomes. It is possible to predict GPI anchor attachment sites from sequence using bioinformatics tools.

Goldberg–Hogness Box, Hogness Box *See* TATA Box

GPI Anchor *See* Glycosylphosphatidylinositol Anchor

Graph, Directed *See* Directed Graph

Graph Theory The branch of mathematics that is concerned with the study of graphs. A graph is defined as an array of points (vertices or nodes) that are connected by lines (edges or arcs). In bioinformatics, graph theory may be used, for example, to analyze the expression patterns of a group of genes. If the edges have a direction (e.g., representing the fact that one gene controls the expression of another), the graph is termed a directed graph.

Greedy Algorithm An algorithm that always takes the best immediate, or local, solution while finding an answer. Greedy algorithms find the overall, or globally, optimal solution for some optimization problems, but may find less-than-optimal solutions for some instances of other problems.
Source: Black, Paul E., NIST Dictionary of Algorithms and Data Structures.

Grid Computing The Grid has been termed “the second-generation Internet”. It is a vision, which is slowly becoming realized, of networked computers set up so

that processing power is as accessible as data is (via the World Wide Web) today. Each computer linked to the grid will be able to "plug in" to a range of services including processing power, communications and storage facilities. The so-called "at home" services in which "spare" PC power is used to solve complex problems, such as Folding@Home in protein folding, are early examples of grid computing. Bioinformatics protocols haved already been set up using the grid.

Hairpin A structural element in either protein or RNA in which a linear chain folds back on itself forming a relatively straight piece of structure with a short loop at one end. In proteins, the two linear regions of chain are beta strands held together with main chain–main chain hydrogen bonds, and the structure is also known as a beta hairpin. In RNA, the linear regions are held together by base pairing, and the structure may also be known as a stem-loop.

Hamming Distance In information theory, the Hamming distance is the number of positions in two character strings where the characters are not identical. The strings are of equal length. This has obvious implications for sequence comparison and pattern matching of genes and proteins, for example, the Hamming distance between the two fragments of protein sequence AFDTGH and VGDTGN is three.

Haploblock A block of DNA sequence that is usually inherited as a whole, at least in a specific population: that is, a block of sequence where linkage disequilibrium is low. The identification of haploblocks is of great value in identifying and mapping genetic associations for complex diseases.

Haploid A eukaryotic cell is described as haploid if it contains only one copy of each chromosome. Thus, a human haploid cell contains one copy of each of the 22 autosomes and one sex chromosomes (either X or Y), making 23 chromosomes in all. Normal gamete (egg and sperm) cells are haploid.

Haploinsufficiency The reduction in gene dosage caused by the mutation of one allele of a gene such that the mutated allele cannot be expressed (i.e., the mutant protein is nonfunctional, truncated, or rapidly degraded). The nonmutant allele, however, is synthesized normally, resulting in the concentration of that protein in a cell being approximately half the normal concentration.
Source: Kahl, G, The Dictionary of Gene Technology.

Haplotype The specific pattern and order of alleles on a chromosome (a specific strand of DNA). Haplotypes tend to be conserved from generation to generation; in particular, alleles that are located close together on a chromosome are likely to be inherited together.

Haplotype Map A map of a chromosome showing the location of specific haplotype blocks. A haplotype block is a block of alleles that are normally inherited together: that is, a stretch of DNA between two areas of high linkage disequilibrium. Haplotype mapping may be used for the detection of genes associated with common, multigenic disorders.

Haplotype tag SNP, htSNP *See* Tag SNP

Helix Bundle *See* Alpha Bundle

Helix Packing The way in which alpha helices pack together in protein structures, to maximize the attractive interactions between the helices. The helix side chains pack together in a way described as the "knobs in holes" model; interhelical angles of 20 degrees (as in four-helix bundles) and 50 degrees (as in the globin family) are preferred.

Heterochromatin This term may be used to mean, either, the part of chromatin that is maximally condensed in interphase nuclei, replicates late in the S phase and is mostly transcriptionally inactive (such as satellite DNA); or, in a different context, the DNA content of the sex-linked chromosomes (such as human X and Y), which are sometimes termed heterosomes or heterochromosomes.
Source: Kahl, G, The Dictionary of Gene Technology.

Heteroduplex Any double-stranded nucleic acid molecule (or duplex) in which the two strands have different origins, whatever those origins are; they may be DNA sequences arising from different genomes or from paralogous genes in the same genome, or they may be an mRNA with its parent DNA. Heteroduplexes may contain loops of single-stranded material lacking a complementary sequence on the opposite strand.

Heterologous Gene Any gene that has been isolated from one organism and transferred into another (i.e., a transgene). Heterologous genes may be contrasted with homologous genes, which are genes that have been taken out of one organism, manipulated (e.g., by introducing site directed mutations) and then transferred back into the same organism.
Source: Kahl, G, The Dictionary of Gene Technology.

Heterozygote Advantage A case where the disadvantage conferred on homozygotes for a particular allele is balanced by an advantage conferred on heterozygotes. If heterozygotes have sufficient survival advantage over individuals without the allele, the allele will increase in frequency despite poorer survival of those with two copies. The allele for sickle cell hemoglobin is a well known example: heterozygotes (with so-called sickle cell trait) are less susceptible to malaria than those without the trait, which balances the disadvantage of homozygotes suffering from sickle cell anemia.

HGP *See* Human Genome Project

Hidden Markov Model A complex, powerful probabilistic prediction technique that has many applications in bioinformatics: for example, predicting gene structure from DNA sequences, protein secondary structure from protein sequences, and classifying genes and proteins into families. The algorithm involves the prediction

of hidden states (e.g., whether a particular base is or is not coding) based on observable ones (e.g., the nucleic acid sequence).

High Pressure Liquid Chromatography HPLC is a very commonly used separation technique with many applications in biotechnology, particularly in proteomics. A complex mixture is passed through a matrix material under high pressure, which separates the components of the complex by mass. HPLC is used for protein separation, protein and nucleic acid purification, and peptide sequencing.

Histone Histones are basic proteins that bind DNA and that are used to package long DNA molecules into the nuclei of eukaryotic cells. This must be a complex process as the average length of a human chromosome when extended is 4–5 cm. DNA-histone complexes are termed chromatin. Posttranslational modification of histone sequences has been implicated in imprinting.

HMM *See* Hidden Markov Model

Holocentric During mitosis, the chromosomes of some eukaryotic species bind to the microtubules along their entire length, and move from there to the poles broadside. These chromosomes are termed holocentric, in contrast to monocentric chromosomes, which bind to the microtubules at the centromere and move toward the poles with that leading. The majority of eukaryotic species, including most model organisms, have monocentric chromosomes; however, the chromosomes of the nematode *C. elegans* are holocentric.

Homeobox A family of genes involved in the control of development in eukaryotes. They code for transcription factors that have been implicated in the formation and differentiation of many tissue and organ types. Homeobox gene sequences are well conserved throughout the evolutionary history of eukaryotes and they have been used to study mechanisms of evolution.

Homeostasis Briefly, homeostasis is the maintenance of equilibrium, or resistance to change. It is a feature of living organisms at all levels, from the molecular, through the cellular to the level of the whole organism. In higher eukaryotes, the maintenance of equilibrium is complex and requires the interaction of many different feedback mechanisms. The mechanisms by which the presence of a metabolite can inhibit the enzyme reactions necessary for its production are very simple examples of these.

Homolog Gene or protein sequences are defined as homologs (or homologous sequences) if and only if they are related by divergent evolution from a common ancestor. Sequence analysis programs determine the degree of identity between sequences; homology can only be inferred from probability, often using functional information.

Homologue *See* Homolog

Homology Modeling A technique for predicting the structure of a protein from its sequence using one or more structures of homologous proteins. This is the most accurate method of predicting protein structure, and can be as accurate as a medium resolution X-ray crystal structure. It is based on a multiple alignment of the test sequence with the sequences of known structure. Generally, conserved regions of structural or functional importance are copied from one of the known proteins and loops are then modeled separately.

Homoplasy Any similarity between two or more sequences (gene or protein), or two or more phenotypic traits, that is not an indication of a common evolutionary origin. Convergent evolution, where the same or a similar solution to a particular problem arises independently more than once, is an example of a process that may lead to homoplasy.
Source: Kahl, G, The Dictionary of Gene Technology.

Horizontal Gene Transfer *See* Gene Transfer

Hot Spot *See* Recombination Hot Spot

Housekeeping Gene A gene that is constitutively active in all cells of an organism and at most developmental stages, because the protein that it encodes is essential for the maintenance of life (e.g., an enzyme that forms part of a general anabolic or catabolic pathway). The concentration of the proteins encoded by these genes is kept at a fairly constant level within the cell. Genes that are only active under some conditions are termed inducible genes. One classic example is the COX family of enzymes; COX-1 is a constitutive gene, whereas COX-2 is induced as part of the inflammatory response.

HPLC *See* High Pressure Liquid Chromatography

Human Genome Project Trivially, the project to sequence the human genome. It was set up in 1990 and expected to take 15 years; however, thanks, largely, to the rivalry between the original public collaboration led by Drs Francis Collins at the NIH and John Sulston at the UK's Sanger Institute, and the private company Celera Genomics founded by Craig Venter it finished 2 years ahead of schedule. The working draft was published in February 2001 and the complete sequence in April 2003. All human genome data is now freely available.

Hybridization The formation of a nucleic acid duplex from two complementary (or near complementary) single strands, either naturally or induced. Hybridization experiments are used to detect sequence similarities and form the basis of microarray technology. In this, which is one of the mainstays of modern bioinformatics, mRNA molecules are detected by hybridization with fragments of complementary cDNA, immobilized on the microarray (or so-called "DNA chip").

Hydropathy plot *See* Hydropathy Profile

Hydropathy Profile A graph that plots the average hydrophobicity of a segment of a protein chain against the amino acid at the centre of that segment. The average hydrophobicity is calculated from the amino acid content of the segment using a hydrophobicity scale. In most widely used scales, very hydrophobic amino acids are given high positive scores, so hydrophobic regions of the sequence – which may, for example, represent transmembrane regions – are represented as "peaks" on the hydropathy plot.

Hydrophobicity Hydrophobic literally means "water-hating". Molecules that are hydrophobic (such as hydrocarbons) are more soluble in oily solvents, such as octanol, than they are in water. Over a third of the amino acids that occur naturally in proteins are hydrophobic; phenylalanine, leucine, and valine are good examples. The fact that these amino acids will be driven into the interior of the protein, away from the solvent, is one of the principal factors driving protein folding.

Hydrophobic Effect The force that drives hydrophobic molecules or parts of molecules (such as hydrophobic side chains in amino acids) away from solvent molecules and into contact with other hydrophobic molecules. The hydrophobic effect drives the formation of the hydrophobic core of globular proteins and is the principal force driving their folding. The solvent accessible surface of proteins is principally formed by hydrophilic amino acids.

Hydrophobic Moment Many alpha helices are significantly amphipathic, with hydrophobic amino acids clustered on one side of the helix and polar and charged ones on the other. In protein structures, amphipathic helices will often be found with the hydrophobic face pointing toward the more hydrophobic environment (the interior of a soluble protein or the lipids of a cell membrane). The hydrophobic moment of a helix is a mathematical concept that measures amphiphilicity, and that is used in protein structure prediction. It is determined by summing the set of vectors in the direction of each amino acid with lengths proportional to their hydrophobicity.

Hypomorphic Allele An allele that produces a protein that has the same function as the wild type protein but with a reduced level of activity, or, alternatively, an allele that produces the wild type protein at lower levels of expression. There will be serious consequences if the function of that gene product is concentration dependent. Hypomorphic alleles are produced by hypomorphic mutations.

Immobilized pH Gradient A polyacrylamide support matrix, which contains chemically immobilized carrier ampholytes such that a stabilized pH gradient is generated along the strip. IPGs allow the separation of larger amounts of protein than is possible using conventional isoelectric focusing techniques.
Source: Kahl, G, The Dictionary of Gene Technology (Second Edition).

Immunocytochemistry A technique that uses antibody-antigen binding to prove protein expression and locate a protein within a cell or tissue. Proteins are located using specific antibodies that are conjugated to dye molecules, and the dye located

under a microscope. All techniques that use dye stains for molecular localization are collectively termed cytochemistry.

Immunodetection *See* Immunoprecipitation

Immunoglobulin *See* Antibody

Immunoprecipitation Any method for locating specific protein antigens in cells or tissues using an antibody that is specific for that antigen that is conjugated with a peroxidase. The antibody-antigen complex is detected by, for example, the peroxide-dependent conversion of luminol, which is accompanied by the emission of light.
Source: Kahl, G, The Dictionary of Gene Technology (Second Edition).

Imprinting Loosely, a phenomenon in which the phenotype expressed by an allele differs according to the sex of the parent who passed on that chromosome. In mammals, the term is usually restricted to those cases where the gene from either the material or the paternal chromosome is inactivated. The gene in question can be referred to as an imprinted gene. In some cases, the phenotype of a genetic disease will depend on whether the defective gene was inherited from the mother or the father. Imprinting is thought to derive from epigenetic differences between the maternal and paternal alleles.

Imprinting Centre Imprinting is a phenomenon in which the phenotype expressed by an allele differs according to the sex of the parent who passed on that chromosome. It arises because some genes from either the maternal or the chromosome are normally inactivated during germ cell development. The chromosomal regions that determine this are known as imprinting centres. Deletions of and errors in imprinting centres give rise to inappropriate imprinting and therefore to genetic disorders.

Indegree In graph theory, the indegree of a node in a directed graph is the number of edges that terminate at that node. This is often applied to the analysis of gene networks derived from microarray experiments, where the relationship denoted by an edge is that one gene affects the transcription of another. A gene with a high indegree is one that is affected by many others, that is, which is highly regulated. Experiments with yeast microarrays have found that most of the genes with high indegree are involved in metabolism.

Indel A shorthand way of expressing “insertion or deletion” in a sequence alignment, expressing the fact that it is impossible to tell (at least without very detailed phylogenetic analysis) whether a gap in an alignment arose from an insertion in one sequence or a deletion in another. In some contexts, the word “indel” may be used synonymously with “gap”.

Index Case In studies of infectious disease, the index case is the first person to become infected with a disease, and so the source of the outbreak. In studies

of genetic disease, the term has been generalized to mean the affected individual through whom an inherited disease-causing mutation is identified in a family.

Inducer A chemical substance, generally of low molecular weight, that binds to a regulator protein and alters its activity in such a way that the transcription of a specific gene or operon, which has previously been repressed, is reactivated. The generic term "effector" is used to indicate a chemical that binds to a regulator and so controls its activity.
Source: Kahl, G, The Dictionary of Gene Technology.

Integrative Biology Integrative biology is often used as a synonym for systems biology. As such, it can be defined trivially as the computer-based analysis or simulation of molecular data within the context of a system. A system may be as (relatively) simple as a metabolic or regulatory network within a single cell, or it may be a cell, tissue, organ, or organism. Integrative or systems biology may therefore include models of different types and of different levels of precision.

Interphase In the cell cycle, the period between cell divisions in which the chromosomes are in an extended form within the cell nucleus and cannot be distinguished separately. Interphase is the phase of the cell cycle during which cells grow and carry out their functions. Cytogenetic tests such as FISH are easier if they can be carried out during interphase, as cell culture is not necessary, but chromosomal abnormalities can usually not be identified.

Intron Those sequences within a eukaryotic gene that are not conserved during pre-mRNA processing and so do not make up the mature message. The introns on the 5′ and 3′ ends of the mRNA may contain sequences that signal initiation or termination of processing, respectively. Prokaryotic genes do not contain introns.

Inverse Problem *See* Inverse Protein Folding Problem

Inverse Protein Folding Problem The problem of finding sequences that conform to (i.e., that are likely to fold into) a given protein topology. It is so-called because it is the inverse of the more common problem of finding the structure that a particular sequence is likely to fold into.

Inverted Terminal Repeat Sequence motifs that flank transposons and that are identical or partly identical and present in inverse orientations. Their function is as recognition sites for the excision of transposons.
Source: Kahl, G, The Dictionary of Gene Technology (2nd Edition).

Ion Mirror *See* Reflectron

Ion Trapping A term used for a group of mass spectrometry methods that are able to measure masses of, for example, peptide ions, with very high precision and accuracy. The peptide ions may be created by any standard MS method (e.g., MALDI or ESI); they are focused into the helium-filled ion trap using an

electrostatic lens. The positions at which the ions are stably trapped depends on the equipment parameters and their mass/charge ratios, and this enables the *m/z* ratios to be calculated.

IPG *See* Immobilized pH Gradient

Isobaric Residues Amino acid residues that have the same molecular mass, and that therefore cannot be distinguished in peptide sequencing using mass spectroscopy (e.g., leucine and isoleucine) are termed isobaric residues.

Isoelectric Point The isoelectric point of a protein is defined as that point on the pH scale where its net positive and negative charge(s) equal zero. During electrophoresis, a protein migrates to a position on a stabilized pH gradient where the pH is equivalent to its isoelectric point.

Isoenzyme *See* Isozyme

Isozyme Multiple forms of the same enzyme, which catalyze the same reaction, but may differ in amino acid sequence, physical properties, and regulation. Isozymes may consist of complexes of different, possibly randomly selected, polypeptide chains. They may be separated by conventional biochemical methods.

Iterative Improvement An algorithmic technique that solves a problem by repeatedly estimating a "slightly wrong" solution, estimating the slight error and subtracting it from the wrong solution to give an improved solution. The process is repeated until the error is smaller than a set value.

ITR, Terminal Inverted Repeat, TIR *See* Inverted Terminal Repeat

Karyotype The complete set of chromosomes in a cell, an individual or a species. The karyotype of a cell or an individual will include gross chromosomal abnormalilties (e.g., in chromosomal number). The word karyotyping is used to describe, generically, a number of techniques for determining the karyotype of an individual; FISH is one example. These may be used to detect aneuploidies such as trisomy 21 (Down's syndrome).

Knockout An informal term for an animal model (very often, but not invariably, a mouse) in which a single gene has been inactivated (silenced or "knocked out") by either random or site directed mutagenesis. Phenotypically, gene knockout animals range from normal to nonviable (i.e., embryonic lethal mutations). The term "knock-in" may be used to describe a model in which the function of an inactive gene is restored by mutation.

Knockout Model, Animal Knockout *See* Knockout

Laboratory Information Management System *See* LIMS

Lagging Strand The DNA strand that is discontinuously synthesized in a 5′ to 3′ direction away from the replication fork during DNA replication. It contains the ligated Okazaki fragments that are linked by ligases to form a continuous strand: each of these is several thousands of nucleotides long in prokaryotes or several hundred nucleotides long in eukaryotes.
Source: Kahl, G, The Dictionary of Gene Technology.

LC *See* Liquid Chromatography

LC-MS/MS *See* Liquid Chromatography/Mass Spectroscopy

LCR *See* Locus Control Region

Leading Strand The DNA strand that is continuously synthesized in a 5′ to 3′ direction toward the replication fork during DNA replication. The opposite strand is the lagging strand, which is synthesized discontinuously.
Source: Kahl, G, The Dictionary of Gene Technology.

Leucine-rich Repeat Short amino acid sequence repeats with a high proportion of leucine residues that are found in tandem arrays in many proteins from different functional families. They are believed to provide a versatile structural framework for the formation of protein–protein interactions, and to be necessary for cytoskeleton morphology and dynamics.

Ligand A generic term for a nonprotein molecule that must be bound to a protein in order for that protein to function. Ligands are usually, but not always, of low molecular weight. In receptor theory, the term ligand is used to indicate the naturally occurring compound that binds to the receptor in order to elicit a response, as opposed to an agonist or antagonist that is added artifically. However, the term may be used to indicate, for instance, an enzyme inhibitor.

Ligase Chain Reaction An in vitro DNA amplification procedure that uses the enzyme DNA ligase to amplify a template. A pair of synthetic oligonucleotides is allowed to anneal to adjacent complementary regions of one strand of the target double stranded DNA, and two other oligos anneal to adjacent complementary regions of the other strand. Each pair of oligos is ligated by DNA ligase, and the ligation product used as a template for subsequent ligation cycles.
Source: Kahl, G, The Dictionary of Gene Technology.

Ligation Amplification Reaction *See* Ligase Chain Reaction

LIMS Computer software used for the automatic management of laboratory functions, which could involve anything from the management of samples and standards to invoicing. LIMS as used to control workflow in complex biotechnology laboratories can be considered a branch of bioinformatics, but it is currently only used to any extent in an industrial context, such as managing high-throughput screening in the pharmaceutical industry.

Lineage Any group of individuals that are derived from a common ancestor may be termed a lineage. Thus, in phylogenetics, the term lineage is synonymous with clade. However, lineage is also used to refer to a family of individual (human or nonhuman) organisms, or, alternatively, a population of differentiated cells derived from an individual precursor (as in "tumour cell lineage").

Linear Ion Trap Ion trapping is a mass spectrometry method that are able to measure masses of, for example, peptide ions, with very high precision and accuracy and in which the peptide ions are focused into the ion trap using an electrostatic lens. A linear ion trap is an enhancement that reduces the number of dimensions of the ion trap from three to two; the ions are trapped radially by a radio frequency containment field, but axially by a static electric field. Linear traps have increased efficiency, sensitivity, and dynamic rang.

Linear Trap *See* Linear Ion Trap

Linkage Analysis *See* Linkage Mapping

Linkage Disequilibrium The occurrence of two or more linked alleles together at a higher frequency than would be expected from their individual frequency in a particular population. The tighter the genetic linkage between a pair of loci is, the higher degree of linkage disequilibrium is observed.
Source: Kahl, G, The Dictionary of Gene Technology.

Linkage Disequilibrium Mapping *See* Association Mapping

Linkage, Glycosidic *See* Glycosidic Linkage

Linkage Mapping The process of deriving a linkage map (or genetic map) of a chromosome location from DNA samples from related and nonrelated individuals, plotting the relative positions of markers based on the frequency of crossovers or recombinations. The genetic distance between two markers – that is, the average number of crossovers during meiosis at the two loci – is given in centiMorgans (cM).

Lipid Raft A small area within a cell membrane that is particularly rich in different kinds of lipids: glycolipids, sphingolipids, and cholesterol. Lipid rafts also contain proteins embedded in the membrane using GPI anchors. Many of these proteins are involved in cell signaling, and lipid rafts are also thought to play a role in signaling processes. They are found in both prokaryotic and eukaryotic cells.

Lipophilicity *See* Hydrophobicity

Lipoplex A complex formed between cationic lipids and DNA, used in nonviral vectors for gene therapy. Complexes formed by cationic polymers for the same reason are termed polyplexes. The DNA in both these types of complexes

is protected from degradation by nucleases. Cationic lipids are very useful as components of gene therapy vectors as they are easy to prepare and characterize.

Liquid Chromatography Any separation technique in which a liquid sample of a complex mixture is passed through a column containing a matrix in such a way that the components of the mixture are separated (e.g., according to their mass). High pressure liquid chromatography (HPLC) has many applications in proteomics and in biotechnology in general.

Liquid Chromatography/Mass Spectroscopy A reliable method for the separation and identification of proteins, involving linking the output from a liquid chromatographic system to a mass spectrometer. Separation of proteins using liquid chromatography is considered to be competitive with the more widely used 2D-PAGE method. Often, the mass spectrometry step is repeated, leading to protein identification: hence LC-MS/MS.

Local Alignment Any pairwise sequence alignment technique in which the assumption is made that the (gene or protein) sequences are not homologous along their entire lengths. Local alignment programs report one or more regions of sequence similarity; where multiple regions are reported, these do not necessarily need to be in the same order in both sequences. This method is appropriate for, for example, aligning whole genes with partial ones, cDNA sequences with genomic DNA, or single domains within multidomain proteins.

Locus The locus of a gene is its location on a chromosome or on a gene map. A single locus may contain several contiguous genes, which are likely to be functionally and/or evolutionarily related: for example, the human cytochrome P450 3A locus on chromosome 7 contains the genes for three different CYP450 isoforms and related pseudogenes.

Locus Control Region Any DNA sequence that exerts a dominant, activating effect on the transcription of genes in a large chromatin domain (10–100 kb). LCRs prevent the influence of heterochromatic silencing on neighboring sequences. They are therefore used in transgenic experiments as insulator elements that protect themselves and linked genes against the repressive action of heterochromatin.
Source: Kahl, G, The Dictionary of Gene Technology.

LOD Score A mathematical description of genetic linkage. The LOD score is defined as the logarithm (to base 10) of the ratio of probabilities that the observed results are produced by linked or unlinked loci. A LOD score of 3 or more indicates that the loci are linked.
Source: Kahl, G, A Dictionary of Gene Technology.

Log of Odds Score *See* LOD Score

Long-branch Attraction In phylogenetic analysis, a phenomenon that is thought to bias any attempt to root the universal tree of life toward a eubacterial root. Since,

in a universal tree, the eubacterial brance is always the longest one, its selection as the universal root may be explained by an attraction between this branch and the long branch of the outgroup.

Long Terminal Repeat The repeat sequences at the ends of a retroviral nucleic acid. In proviruses, the upstream LTR functions as a promoter/enhancer and the downstream LTR as a poly-A addition signal. Long terminal repeats are several hundreds of base pairs in length and the repeated sequence is of 4–6 bp. These sequences can be used as elements of integration vectors.
Source: Kahl, G, The Dictionary of Gene Technology.

Low Complexity Regions Regions of DNA or protein sequence that either repeat a single residue or short residue pattern, or else contain a much higher than average percentage of a particular residue type. In gene sequences, low complexity regions are often microsatellites; in protein sequences they may represent, for example, glycine or cysteine rich regions. Low complexity regions are often masked (ignored) in sequence alignments and searches because they may generate spurious (unrelated) matches.

LTR *See* Long Terminal Repeat

Luciferase An enzyme, isolated from fireflies and some bacteria, which catalyzes the decarboxylation of D-luciferin to oxyluciferin. This reaction generates a flash of light, which can be easily monitored. Luciferin is often used to monitor protein expression, particularly in transgenic cells.

Luciferin Any compound that is a natural substrate for the luminescent enzyme luciferase, which is used in proteomics as a reporter for gene expression. Structurally unrelated substrates of luciferase have been isolated from various species including the firefly *Photinus pyralis* and the ostracode Cypridina. These are generally medium-sized organic molecules containing aromatic heterocycles.
Source: Kahl, G, The Dictionary of Gene Technology.

M, 100 centiMorgans, 100 cM *See* Morgan

Machine Learning An area of artificial intelligence in which a computer is allowed to "learn" the pattern and structure of a dataset by analyzing it, and use that to classify data not in the original dataset. Machine learning overlaps significantly with statistical analysis. It is more popular than other areas of artificial intelligence in modern bioinformatics, finding applications in sequence analysis and in the analysis of microarray data.

Main Chain The backbone of a polypeptide chain, consisting of linked peptide groups and alpha-carbon atoms: thus, the main chain atoms of a single amino acid can be written using standard terminology as –C(O)–C–N(H)–. The peptide group is planar, which restricts the geometric conformation of the main chain. It

is the side chains bonded to the alpha-carbon atoms that give the amino acids, and therefore the proteins, their chemical diversity.

MALDI *See* Matrix Assisted Laser Desorption/ionization

Malecot Model An algorithm for prediction of the decay of linkage disequilibrium with distance, using three parameters. Distance can be measured either in centimorgans or, if it can be assumed that recombination is uniform over the region, in kilobases.

Map-based Cloning; Map-assisted Cloning; MAC *See* Positional Cloning

Markov Chain Analysis *See* Markov Model

Markov Model A probabilistic statistical model used in many bioinformatics applications. One example is its use in sequence analysis, where the probability of each nucleotide or amino acid occurring is dependent on those preceding it. A hidden Markov model (HMM) is a Markov model in which one or more variables are hidden.
Source: Westhead et al, DR, Instant Notes in Bioinformatics.

Mass/charge Ratio *See* m/z Ratio

Mass Fingerprint *See* Peptide Mass Fingerprint

Mass Resolution The extent to which a mass spectrometer can distinguish between samples of similar mass. Modern Fourier Transform mass spectrometers have very good mass resolution, being capable of identifying peptides and even distinguishing between isotopes.

Mass Spectrometry In proteomics, mass spectrometry is used to identify proteins from small samples that have been separated by, for example, 2DPAGE. The proteins are first fragmented into peptides using proteases (typically trypsin). Mass spectroscopy involves the ionization of the peptide sample, the separation of the ions by mass-charge (m/z) ratio, and the analysis of the separated ions and identification of the protein from its constituent "peptide fingerprint". Different technologies exist for peptide ionization (e.g., MALDI and ESI), ion separation (e.g., time-of-flight) and mass fingerprint analysis.

Mass Spectrometry, Tandem; Tandem Mass Spectroscopy; MS/MS *See* Tandem Mass Spectrometry

Mass Tolerance A measure of the precision expected from a mass spectrometry experiment, which is used in determining whether, for example, an experimentally measured ion corresponds to a certain peptide. The Mowse scoring algorithm for MS matches states that "each calculated value which falls within a given mass

tolerance of an experimental value counts as a match". Typical mass tolerance values are 2.0 a.m.u. for peptides and 0.8 a.m.u. for fragment ions.

Matrix Assisted Laser Desorption/ionization A technique used in protein mass spectroscopy, as applied to the analysis and identification of separated proteins obtained in proteomics experiments (e.g., 2DPAGE). A solution of the digested peptides is passed through a thin needle with a nebulizing gas, and a high voltage applied to the tip. This generates a spray of droplets containing ions. The droplets evaporate leaving peptide ions that pass through a series of electrodes and samplers to the mass analyzer, which usually works on the time-of-flight principle.

Maximum Likelihood A statistical method pioneered by a geneticist, Sir Ronald A. Fisher. It is a method of point estimation that estimates the value of an unobservable parameter as that value that maximizes the likelihood function. The log of the likelihood (the log-likelihood) is an often quoted value.

Maximum Parsimony One of three methods commonly used in phylogeny to select the most probably phylogenetic tree relating a set of sequences. In maximum parsimony, the "correct" tree is assumed to be the one that minimizes the number of step changes (i.e., single base or amino acid changes) from the presumed common ancestor that are needed to complete the tree. It generates unrooted trees; it is a very reliable method, but is time consuming and CPU intensive, so best used with small numbers of similar sequences.

MCS *See* Multispecies Conserved Sequence

MD *See* Molecular Dynamics

Membrane Anchor A single segment of protein chain that either embeds in, or passes through, a cell or organelle membrane, anchoring the protein to that membrane. Proteins containing membrane anchors must contain either a cytoplasmic or an extracellular functional domain, and may contain both these: the function of the anchor is to attach that protein to a particular point at the surface of the cell or organelle. If such a protein contains more than one domain, the anchor is bound to act as a domain boundary.

Membrane Protein A protein that passes through a cell membrane, either once or more than once. Apart from proteins that are embedded in the outer membranes of Gram negative bacteria, which are beta-barrels, all membrane proteins contain one or more transmembrane helices. Type I and type II membrane proteins have a single transmembrane helix separating extracellular and cytoplasmic domains. Integral membrane proteins contain helix bundles that are embedded in the cell membrane. Some types of membrane protein contain signal anchor sequences towards their N-terminal ends.

MEMS *See* Microelectromechanical Systems

Mendelian Disease A genetic disease or disorder that is carried by a single gene. Mendelian diseases have a penetrance approaching 100%, that is, all people who carry an abnormal variant of the gene on one or more alleles (depending on the inheritance pattern) will suffer the disease to a greater or lesser extent. Examples include cystic fibrosis (recessive inheritance), Huntington's disease (dominant inheritance), and hemophilia (sex-linked inheritance).

Metabolic Pathway The linking of small, biosynthetic molecules via the enzymes that synthesize them in the normal metabolism of any species, to form a network; one widely studied example is the glycosidic pathway through which glucose is hydrolyzed to pyruvate with the release of ATP (energy). Information about metabolic pathways is held in databases including KEGG and WIT.

Metabolomics The study of the metabolome. This is defined, by analogy with "genome" and "proteome" , as the sum total of all metabolites (the "small molecules" that are substrates, intermediates and products in metabolic reactions within a cell. Like the proteome, the metabolome varies between cell types and, within a cell type, according to developmental stage and environmental conditions.

Meta-Data Data held within a database that is accessory to and associated with the primary data in the database. For example, the metadata held in a protein sequence database might include gene name and chromosomal location, Gene Ontology annotations, enzyme activity and metabolic pathway involvement. The term metadata may also be used to describe information about an HTML document that is held within the file but not displayed by a browser.

Metadata *See* Meta-Data

Metaphase The phase during eukaryotic cell division (mitosis or meiosis) between prophase and anaphase, in which the nuclear membrane has broken down and the daughter chromosomes align in the center of the cell before being drawn toward its ends by the microtubules. This is the stage in mitosis when the chromosome pairs are most clearly visible, so it is useful for cytogenetic analysis.

Meta Server A server on the Internet that provides access to a number of other servers that provide programs with very similar functions (but probably different methodologies), for example, protein structure prediction, allowing users to compare the results of the different programs. Groups that provide meta servers often do not provide their own methods, but do give anaylsis of the different methodologies.

Metric Map Any map of a genome or chromosome, whether defined by linkage, marker or polymorphism, in which the distance between the elements is recorded as well as their order. Linkage disequilibrium maps may be made into metric maps when the linkage disequilibrium is plotted against the physical distance between markers on the chromosome.

MIAME A series of guidelines set up by the MGED (Microarray Gene Expression Data) Society to enable sharing of microarray data within the gene expression profiling community. The guidelines are designed so one group will be able to reproduce exactly a microarray experiment produced by another. This has been facilitiated by the invention of an XMA format markup language, MAGE-ML, for the storage of microarray data.

MIAPE A series of guidelines set up by the Human Proteomics Society, by analogy with the MIAME guidelines for microarray experiments, to enable sharing of proteomics data within the community. The guidelines are designed so one group will be able to reproduce exactly a proteomics experiment produced by another.

Michaelis–Menten Equation

Microarray An ordered array of (usually) cDNA fragments, arranged at extremely high density on a solid support, and used for analysis of the mRNA content (transcriptome) of a cell. The experiment is set up so that a signal is generated if the sample contains mRNA molecules that can hybridize to a given cDNA.

Microchimerism A relatively common phenomenon in which cell lines with different chromosomal compositions are found in one individual. Unlike mosaicism, however, in microchimerism, the cells are derived from two separate individuals. Sometimes cells are exchanged between twin fetuses in the uterus (so-called twin-to-twin transfusion); more often, there is an exchange of cells between mother and fetus during pregnancy, and the mother's cells may persist throughout the lifespan of the offspring. Microchimerism has been implicated in a number of autoimmune diseases.

Microelectromechanical Systems Extremely small, microfabricated electrophoresis systems that have been proposed as a potential solution to the remaining cost limitations of genome sequencing. The technology requires multichannel devices and the ability to process samples on the nanoliter scale. Many such devices have short read lengths and these may be most suited to resequencing or genotyping.

Micro-RNA *See* miRNA

Microsatellite Any short (typically 1–6 bp) tandem repeat in a genome sequence, that is, any short base pattern repeated a number of times. Microsatellites are common throughout eukaryotic DNA. They are often "masked" in sequence searches because a microsatellite match may swamp a match to a distant homolog. Most microsatellites occur in intergenic DNA (so-called "junk DNA") but occasionally one occurs in a coding region, for example, the (CAG)n motif in the huntingtin gene which is expanded in Huntington's disease patients.

Middleware A type of software that is used as an intermediary between different components; for example, the different components of software that sit between a

database user on a client system and the database server. There is a sense in which an ontology can be described as a piece of middleware.

Minimum Information about Microarray Experiment *See* MIAME

Minimum Information about Proteomics Experiment *See* MIAPE

Minisatellite A short, repetitive, usually GC-rich tandemly arranged DNA sequence. Minisatellites (9–64 bp) are longer than microsatellites (1–8 bp). They occur in all eukaryotic genomes, but are more common in large genomes of complex organisms. Minisatellites tend to show significant length polymorphism.

miRNA Very small mRNA molecules, only 20–25 nucleotides long, that are involved in the regulation of gene expression. They are transcribed from DNA sequences, initially as longer sequences that contain the miRNA and an almost self-complementary sequence that forms a hairpin. The mature miRNA is cleaved out of the precursor sequence by enzymes. It is complementary to part of a coding gene and may anneal to the mRNA, preventing protein translation.

Missegregation Any process by which chromosomes fail to segregate correctly during cell division, leading to the formation of daughter cells with abnormal and/or missing chromosomes. Chromosomal missegregation often occurs during the division of cancer cells, leading to further errors. The production of abnormal and even extra spindle poles has recently been implicated in this process.

Missense Mutation An ordered array of (usually) cDNA fragments, arranged at extremely high density on a solid support, and used for analysis of the mRNA content (transcriptome) of a cell. The experiment is set up so that a signal is generated if the sample contains mRNA molecules that can hybridize to a given cDNA.

Mitosis The process of cell division that takes place in eukaryotic cells at all times except gametogenesis, and in which the chromosomes are replicated, maintaining chromosome number. Thus, one diploid cell will – in the absence of replication errors – produce a pair of identical diploid cells.

Model-based Analysis A type of test used in statistical genetics in which the frequency and penetrance of an allele that has been implicated in disease can be estimated with sufficient accuracy to be used in a mathematical model. It is most commonly used for simple genetic diseases; model-free analysis is usually used to model complex diseases. The alternative terms of parametric and nonparametric analyses are regarded as less accurate because some mathematical parameters are generally used in model-free analysis.

Model Organism An organism that is widely studied by geneticists not because of its pathogenicity or utility but as a genetic "model" for higher organisms. Model organisms are generally common, small, and tractable, and have short

life cycles: thus, the nematode word, Drosophila, Arabidopsis and the common laboratory mouse are all model organisms. By 2004, the genomes of most organisms commonly used as models had been made publicly available.

Modular Protein *See* Mosaic Protein

Module Domains within proteins may also be referred to as modules. This terminology is most often used of domains that are relatively small, that are present in many protein families with different functions, and that can occur multiple times in the same protein. The immunoglobulin, SH2, and SH3 domains are examples of domains with these properties.

Molecular Clock The molecular clock hypothesis is the assumption that evolution occurs at the same rate along branches of a phylogenetic tree that emerge from the same node – that is, that branches of a tree that share a common node will be of the same length. It is often a reasonable assumption, particularly if the sequences are closely related, but there are many instances where it cannot be applied because one taxon has undergone more mutations since divergence than another. This hypothesis is built into some phylogeny methods.

Molecular Dynamics A molecular modeling technique in which the motion of a single molecule or, more often, a molecular system (such as a protein and its ligands in a "bath" of solvent molecules) is simulated. This allows a fuller exploration of conformational space than the related technique of energy minimization. Most often, the molecules are described using a simple molecular mechanics force field: nevertheless, it is very expensive in CPU time. Simulations cover times that are typically of the order of nanoseconds.

Monocistronic A messenger RNA is defined as monocistronic if it codes for a single polypeptide chain (i.e., a single protein). An mRNA that codes for more than one protein, such as that produced from a single prokaryotic operon, is said to be polycistronic. The majority of eukaryotic mRNAs are monocistronic.

Monogenic Disease *See* Mendelian Disease

Monophyletic In phylogeny, a taxonomic group is defined to be monophyletic if all organisms in that group are known to be descended from a common ancestor, and if all the descendants of that ancestor are included in that group. Thus, the genus Homo is classified as monophyletic because all organisms in that genus are believed to derive from a common ancestor, and no other descendants of that ancestor occur outside Homo. Taxonomists prefer to define monophyletic groups if at all possible.

Monte Carlo Algorithm A type of numerical method that involves statistical simulation using sequences of random numbers. In bioinformatics, Monte Carlo methods are regularly used, for example, in simulating the motion of a macromolecule or complex.

Morgan A measure for the relative distance between two genes on a chromosome, or for the frequency of recombination between two genetic markers. One Morgan corresponds to that length of chromosome in which, on average, one recombination event occurs each time a gamete is formed. Genetic distances are more usually recorded in centiMorgans (0.01 M).
Source: Kahn, G, The Dictionary of Gene Technology.

Mosaicism A type of genotype in which two cell lines with different chromosomal compositions, derived from a single fertilization, are found in a single individual. Generally, one cell line will be normal and the other contain a chromosomal aberration such as aneuploidy. The resulting phenotype depends on the proportion of abnormal cells as well as the type of aberration, and ranges from normal through minor abnormalities to malformations incompatible with life, posing serious problems in genetic counseling.

Mosaic Protein A protein that is composed of a number of different domains (or modules). Some mosaic proteins contain very large numbers of domains. The domains that are present in many mosaic proteins are often relatively small, and some domains are found in an enormous range of different proteins with a wide variety of functions. A protein containing only 2–4 domains would not be termed mosaic: it is not a synonym for multidomain.

Motif A (generally small) sequence of amino acids within a protein sequence, or bases between a nucleic acid sequence, that are characteristic of a particular family, a generic function or a structural pattern. Examples of protein motifs include the helix-turn-helix and the zinc finger, which both bind DNA. The smallest motifs, which can involve only 3 or 4 amino acids, represent potential locations of posttranslational modifications, The main database of protein motifs is PROSITE.

MS, Mass Spectroscopy *See* Mass Spectrometry

Multiallelic A gene, or a genetic marker that has more than two forms; in contrast, almost all single nucleotide polymorphisms (SNPs) have only two base variants (e.g., a position may be A or T but not G or C) and are therefore termed biallelic. Genotyping individuals at the sites of multiallelic markers can be very useful in the mapping of genes involved with complex diseases.

Multifocal A disease that is present at more than one site in the body (i.e., which has more than one focus) is termed a multifocal disease. Bilateral breast cancer, in which the cancer is found in both breasts, is an example. Where a disease, such as breast cancer, is heterogenous and is only sometimes multifocal, the presence of multifocal disease is one characteristic that can suggest a high genetic component and thence increase risk in blood relatives.

Multigenic Disease A disease or deleterious trait that is caused by mutations in many genes, rather than, as is the case in monogenic disorders, by a single mutation in one gene. Many common diseases, such as asthma, some types of cancer and

some forms of heart disease, are multigenic. The same disease phenotype may have many possible complex genetic causes.

Multiple Alignment An alignment of more than two gene or protein sequences. Each row in a multiple alignment consists of a single sequence padded by gaps, with the columns highlighting similarity/conservation between positions. An optimal multiple alignment is one with the highest degree of similarity between the sequences. CLUSTAL is a commonly used public domain multiple alignment program.

Multiple Marker Screening Any test that involves obtaining values from several different markers and combining their results to predict the most likely outcome. The term is often applied to one particular test: the measurement of alphafetalprotein and hormone levels in an attempt to detect pregnancies with a high probability of Down's syndrome or another genetic abnormality. These tests generally give a large number of false-positive results.

Multispecies Conserved Sequence A sequence – generally a DNA sequence – that is conserved throughout a large number of species, often highly divergent species. Highly conserved regions have been subjected to extremely strong evolutionary pressures, and therefore code for elements that are necessary for the survival of complete clades (e.g., all vertebrates).

Mutagen Any physical or chemical agent that increases the frequency of mutations in DNA above the spontaneous background level. Mutagenic agents include ionizing radiation, UV irradiation, chemicals (e.g., alkylating agents) and nucleotide base analogs. Mutation may take place in the test tube or in vivo.
Source: Kahl, G, The Dictionary of Gene Technology.

Mutagenesis The process of introducing a change – that is, a mutation – into a DNA sequence. Mutagenesis does, of course, occur naturally, and it may be silent (produce no change in the resulting protein). However, the term is most often used to indicate an artificially induced change. Point mutations are introduced into protein sequences via site directed mutagenesis. The term is also used for methodologies used to create strains of transgenic mice (e.g., gene-trap mutagenesis).

Mutagenesis, Site-directed; Site-specific Mutagenesis *See* Site directed mutagenesis

Mutagenic Agent *See* Mutagen

Mutation Any compositional change in a DNA sequence that is not caused by normal segregation or genetic recombination. Mutations may involve base changes (giving rise to single nucleotide polymorphisms), insertions or deletions; they may occur in coding or noncoding sequence. Mutations in coding sequence will lead to a change in the protein sequence unless the change is to a synonymous codon;

mutations in noncoding sequence may have phenotypic consequences if they change the expression patterns of genes.

Mutation, Missense *See* Missense Mutation

Mutation, Nonsense *See* Nonsense Mutation

***m/z* Ratio** The ratio of the mass of a molecular ion to its charge. This is the quantity by which particles are sorted in a mass spectrometer in the separation experiments that are key to peptide identification in proteomics (most usually by time of flight). It is, therefore, important to work out the charge of each species if its mass – by which it is identified – is to be calculated correctly.

N-glycosylation One of two types of linkage between the side chain of an amino acid within a protein and a simple sugar or oligosaccharide. The sugar moiety is attached to the protein chain via a covalent bond between *N*-acetyl-D-glucosamine and a nitrogen atom in the side chain of an asparagine (N) residue which must lie in the context of the simple motif N-X-S/T).

Needleman–Wunsch Algorithm A dynamic programming method of aligning pairs of sequences that produces a global alignment between the whole sequences. The alignment score is defined as the sum of the scores at each individual position; the sequences are moved and gaps introduced to maximize the total score along the sequence lengths. Gap penalties are often, but not always, applied to gaps at the end of sequences. This method is used in, for example, the EMBOSS global alignment program, NEEDLE.

Network Complex relationships between entities may be represented using networks of connections. Each entity (a gene or protein) is represented as a point, or node, in the network, and the relationships between them are represented by lines joining nodes (known as edges). Graph theory is used to classify and cluster the nodes in a network, discovering relationships that may not be visible from a simple examination of the raw data.

Neural Network A programming methodology often used in bioinformatics for predicting features from sequence data (e.g., predicting genes from DNA sequences or protein structure from amino acid sequences). A neural network program consists, simply, of a series of “neurons” that read data (e.g., sequences) and pass information about that data as signals to other neurons; the final neuron makes the prediction. Sequences containing the known features must first be used to “train” the network.

NMR *See* Nuclear Magnetic Resonance

Node In graph theory, the objects are known as nodes, and they are connected by lines indicating relationship; these are edges. The edges may or may not have directionality, depending on the relationship modeled. Graph theory has many

applications in bioinformatics, where is used to cluster the most closely related objects (typically genes or proteins) together. Nodes are most often used to represent individual genes or proteins, connected by relationships such as “is coexpressed by” (for genes) or “interacts with” (for proteins).

Nonsense Mutation Any mutation that converts a sense codon (coding for an amino acid) into a stop codon (TTA, TAG, or TGA in the standard code), or, conversely, a stop codon into a sense codon. This leads to the production of a polypeptide chain that is either truncated or extended, and, consequently, the function of the protein will be either severely limited or completely abolished.

Nonsynonymous A base change (mutation) is described as nonsymonymous if it occurs in coding DNA and gives rise to a change in the amino acid that is coded for: thus, a change from T to A that changes the codon CAT to CAA, and thus changes the amino acid histidine to glutamine in the resulting protein is synonymous, whilst a T–A change that changes CCT to CCA is synonymous as both codons code for proline. Nonsynonymous changes are self-evidently more important in evolution than synonymous ones; they are also less common in coding DNA.

Normalization The equalization of the concentrations of transcripts present in a cell at extremely different levels, balancing the unequal representation of the messages in a cDNA library (which often vary by more than 5 orders of magnitude) by reducing the number of highly expressed mRNAs and enriching rarely expressed message.

Northern Blotting A gel blotting technique in which RNA molecules, separated according to size by agarose or polyacrylamide gel electrophoresis, are transferred directly to a filter by electric or capillary forces. Single-stranded nucleic acids may be fixed to the filter by baking and are thus immobilized. Hybridization of single-stranded probes to the immobilized RNAs allows the detection of individual RNAs out of complex mixtures.
Source: Kahl, G, The Dictionary of Gene Technology.

Nuclear Magnetic Resonance An analysis technique in which molecules are identified, and molecular structures detected, by monitoring signals generated by certain atomic nuclei (those of nonintegral spin, most often protons) in oscillating high magnetic fields. Two-dimensional nuclear magnetic resonance (2D NMR) is often used for determining protein structures. This technique has the advantage of generating the structures of proteins in solution, but the disadvantage that it can only be used with relatively small proteins.

Null Hypothesis In statistical analysis, a hypothesis is chosen at the beginning of an experiment; the objective is to collect enough data to prove or disprove that hypothesis. The null hypothesis states that a condition, for example, that a given proportion of the data has a particular value or range of values, (or will not) be met; the objective of the test is to accept or reject that hypothesis.

O-glycosylation One of two types of linkage between the side chain of an amino acid within a protein and a simple sugar or oligosaccharide. The sugar moiety is attached to the protein chain via a covalent bond between *N*-acetyl-D-galactosamine and the hydroxyl group of a serine or threonine residue in most protein, or of a (nonstandard) hydroxylysine residue in the protein collagen.

O-mannosylation The transfer of a mannose residue to dolichyl activated mannose to serine or threonine residues of secretory proteins, catalyzed by protein *O*-mannosyltransferases. Mannosylation was first observed in fungi, but mannosyltransferase orthologs have now been identified in the genomes of higher eukaryotes.

Object Oriented Programming A programming paradigm, adopted in the programming language C and more modern languages influenced by it including C++ and Java, in which data types are defined as objects. An object includes both data and the operations (functions) that can be applied to it. Most programming languages frequently used in bioinformatics are fully object oriented; one exception is the popular and easy to learn scripting language, Perl.

Obligate Able to live only in a particular set of conditions; that is, an obligate parasite is unable to survive and reproduce outside its host. The bacterium *Chlamydia trachomatis* is an obligate intracellular human pathogen that is unable to reproduce outside human cells.
Source: http://www.biology-online.org/dictionary.asp?Term=Obligate.

Oligo *See* Oligonucleotide

Oligomer A relatively small number of molecular units joined or associated together. These may be covalently bonded, as in nucleotides (to form an oligonucleotide) or amino acids (to form an oligopeptide or, simply, a peptide) or noncovalently associated, as in several protein chains forming a functional protein complex. Associations of two, three and four units are termed dimers, trimers and tetramers respectively. The DNA double helix is, therefore, a noncovalently bonded dimer.

Oligonucleotide A short segment of nucleic acid, which may be single- or double-stranded. The term is generally used for segments containing up to 100 nucleotides or base pairs. The short form "oligo" is almost always used informally by experimental molecular biologists. Oligos may consist of deoxy- or ribonucleotides, or of a mixture of the two.

Oligosaccharide A molecule made up of a relatively small (say 10–100) number of sugar units (=monosaccharides), joined together by condensation reactions to form linear or branched chains. Oligosaccharides are frequently attached to protein molecules to form glycoproteins. Larger numbers of monosaccharide linked together form polysaccharides (also termed complex carbohydrates).

Oncogene Genes that control normal cellular growth and development are known as proto-oncogenes. In normal cells, these are kept under tight control, so growth and development signals are only sent when required. When an oncogene is mutated (by point mutation or simply gene amplification), it can become altered so its protein product is always activated, so growth/division signals are always sent. Uncontrolled cellular growth and development is the hallmark of cancer; the altered proto-oncogene is known as an oncogene.

Ontology In computer science and allied fields, the word ontology – defined philosophically by Aristotle as ”the science of being qua being – is used to describe a strict conceptual schema of data or concepts within a given domain. This has been applied to the derivation of structured, consistent vocabularies in different areas of knowledge, including the life sciences. The most well known ontology in the molecular life sciences is undoubtedly the Gene Ontology (http://www.geneontology.org).

Open Reading Frame Trivially, a region of genome sequence that starts with an initiation (START) codon and ends with a termination (STOP) codon, and so is translated into protein. A scan of a genome sequence for long ORFs is the first and easiest stage of gene prediction. In practice, the situation is much easier in prokaryotic genomes than in eukaryotic genomes, which are complicated by the extreme length of some genes, the presence of introns, and the necessity of identifying splice sites.

Open Reading Frame EST Sequencing *See* ORESTES

Open Source A software product that is not only deliberately given away free, but where the code is made freely available and where modification is not only allowed but encouraged, is termed open source software. It may be protected by agreements that are analogous to the way copyright laws work in the commercial sector; one of these is known as “copyleft”. Examples of open source software products include the Linux operating system for PCs and the general bioinformatics package EMBOSS (European Molecular Biology Open Software Suite).

Operator The stretches of prokaryotic genome sequence, adjacent to the promoter regions of genes, that regulate gene expression by binding proteins. The first regulatory mechanism to be understood was that of the lactose operon: here, it is the binding of the lac repressor to the operator region that prevents the attachment of RNA polymerase and therefore gene expression.

Operon Operons are only found in prokaryotes. They are series of genes, normally functionally related, that are adjacent on the bacterial chromosome, are under the control of a single promoter, and are synthesized into a single, polycistronic mRNA that is translated into the constituent proteins.

ORESTES Normally, ESTs are derived from the $3'$ and the $5'$ ends of cDNAs, and fragments from the centre of transcripts are underrepresented in EST libraries.

ORESTES is a novel technique for generating ESTs that preferentially amplifies the central portion of transcripts, and which can therefore be used to add many novel sequences to EST databases. It involves the amplification of the expressed gene transcripts by reverse transcription-PCR using arbitrarily chosen primers.

ORF *See* Open Reading Frame

Origin *See* Origin of Replication

Origin of Replication The sequence or region on a DNA strand or chromosome where replication begins – that is, the replication-initiation focus. In eukaryotes, the segment of DNA that is under the control of one replication-initiation focus, and which therefore acts as an autonomous unit during replication, is termed a replicon.
Source: Kahl, G, The Dictionary of Gene Technology, 2nd edition (Wiley-VCH, 2001).

Orphan Gene A gene that does not have any known orthologs in any other species – that is, a gene that is, as far as is known, found in one species only. Generally, the function of an orphan gene is unknown. The term is also applied to open reading frames (ORFs) that are not (yet) validated genes, hence the alternative term ORFan. Of course, it is possible that a gene that is thought to be an orphan gene may not be because its homologs are distant enough to be undetectable at the sequence level or because all its orthologs are in genomes that have not yet been sequenced.

Ortholog Two homologous (evolutionarily related) genes are defined to be orthologous (i.e., they are orthologs of each other) if they are essentially the same gene, with the same function, in different organisms. Thus, human hemoglobin, mouse hemoglobin, and sperm whale hemoglobin are orthologs.

Outdegree In graph theory, the outdegree of a node in a directed graph is the number of edges that start at that node. This is often applied to the analysis of gene networks derived from microarray experiments, where the relationship denoted by an edge is that one gene affects the transcription of another. A gene with a high outdegree is one that affects many others, that is, which is a central regulator of the network. Experiments with yeast microarrays have found that most of the genes with high outdegree are transcriptional regulators.

Outgroup A sequence (or group of sequences) included in a phylogenetic analysis precisely because it is known to be more distantly related to the other sequences than any of them are to each other. The outgroup will diverge from the other sequences near the root of a rooted tree. Outgroups are useful as external references, and including one may lead to more accurate ordering of the other sequences.

Pair Potential In molecular mechanics calculations or (much more often) molecular dynamics simulations, parameters to be used in equations defining

the non-bonded interactions between different types of atom. Each pair of atom types will have a different pair potential. The parameters are inserted in a standard equation defining nonbonded interactions (e.g., the Lennard–Jones or the Buckingham potential equation).

Palindrome In the study of language, a palindrome is a word or sentence that reads the same forward as backward, but that nevertheless makes sense: one example is the word MADAM. In genetics and genomics, the word is used analogously to mean a sequence of DNA where identical sequences run in opposite directions, so each strand reads the same in the 5′ to 3′ direction. Palindromic DNA sequences can be the target for DNA binding proteins and they often occur in regulatory regions of DNA.

PAM Matrices One of the two most widely used sets of matrices that hold data on the evolutionary distance between amino acids (i.e., the probability that a substitution of one amino acid by another will be accepted), the other being the BLOSUM matrices. PAM stands for "point accepted mutation" although "accepted point mutation" would be clearer. The PAM 1 matrix is the substitution matrix for a situation where exactly one mutation has occurred per 100 amino acids. The most widely used matrix is PAM 250, which corresponds to approximately 20% identity between the sequences.

Panmixis Simply, random mating – that is, sexual reproduction where the choice of mates is not influenced by their genotypes. The word is derived from the Greek word mixis (mixture).

Paralog Two homologous (evolutionarily related) genes are defined to be paralogous (i.e., they are paralologs of each other) if they have different (although almost always related) functions. They may or may not occur in the same genome: paralogs that occur in the same genome will have evolved through gene duplication. Thus, human hemoglobin and human myoglobin are paralogs, but so are human myoglobin and sperm whale hemoglobin.

Parametric Analysis *See* Model-based Analysis

Parsimony *See* Maximum Parsimony

Pattern Recognition Trivially, any tool or technique for recognizing patterns in sequences. The technique of pattern recognition is most often applied to protein function detection, as short groupings and/or more complex patterns of amino acids often have implications for the function of the protein. The database PROSITE contains data on many hundreds of amino acid patterns that have been associated either with protein families, functions, or (for the shortest patterns) posttranslational modifications.

PCR *See* Polymerase Chain Reaction

Pedigree Simply, a chart or diagram showing the relationships within a human (or model organism) family that can be used to study the inheritance pattern of an allele, marker, or disease. Large pedigrees over many generations and within relatively isolated populations, such as those studied in Decode's Icelandic genome project, have been used to map the loci and alleles involved in complex diseases.

Penetrance A gene is said to have high penetrance if the properties that it codes for will always or almost always be present in the phenotype, and low penetrance if the amount to which it is observed in the phenotype is more dependent on environmental variables. Thus, the CFTR gene has higher penetrance than the BRCA1 gene because a mutation in CFTR will almost always cause cystic fibrosis, whereas one in BRCA1 only increases the lifetime chances of contracting certain cancers.

Peptide Fingerprint *See* Fingerprint

Peptide Mass Fingerprint Analysis of a protein by mass spectroscopy produces a series of masses of the peptides that were generated from the original protein by protease cleavage. Knowing the mass series and the protease used, it is often possible to identify the protein. The mass series is referred to as a peptide mass fingerprint (or mass fingerprint) for the protein concerned. Mass fingerprinting cannot be perfectly reliable because of, for example, the existence of isobaric residues: sequencing at least parts of the fragments is often needed to fully identify the protein.

Peptide Sequence Tag A short string of peptide mass differences corresponding to a peptide sequence that can be used to identify a longer protein. In a technique developed by Matthias Mann and Matthias Wilm at EMBL in the 1990s, mass spectra of protein fragments derived from MS/MS analysis of proteomics experiments are searched for the presence of sequence tags, and these are used to identify the original protein.

Pericentromere The regions of eukaryotic chromosomes that immediately flank the centromere. Like centromeres, pericentromeres contain a large proportion of repetitive sequences and few genes. The pericentromere is a structural domain of the chromosome that is essential for chromosomal segregation; it has been implicated in the cohesion of the chromosome pairs.

Perl A programming or scripting language that is particularly useful for interpreting and reformatting large quantities of textual data. It is available for all common computer platforms; it is regarded as being easy to learn and use and is the programming language of choice of most bioinformatics professionals who were not trained as programmers. Libraries of Perl scripts for bioinformatics tasks (e.g., BioPerl) have been made available.

Phage Trivially, any virus that infects bacteria. Phages are simple viruses, consisting of a core of either DNA or RNA surrounded by a protein coat. Some phages

are virulent; infection with a virulent phage inevitably leads to viral replication, and the death and lysis of the host cell. Other phages, known as temperate phages, may insert their DNA into the host chromosome where it remains transcriptionally silent. Phages have many uses in modern molecular biology.
Source: Kahl, G, The Dictionary of Gene Technology.

Phage Display A technique for the presentation of distinct proteins or peptides on bacterial surfaces, using bacteriophages as carriers. Genes for the proteins to be displayed are integrated into the phage genome, and the proteins expressed as fusions with a viral coat protein. This exposes the display proteins on the bacterial surface. The technique enables the identification of proteins with particular binding properties.
Source: Kahl, G, The Dictionary of Gene Technology (2nd Edition).

Pharmacogenetics The influence of genetics and, especially, of genetic variation, on pharmacology: that is, how differences in people's genetic makeup influence their response to drugs. One important aspect of this is the effect of common polymorphisms in the P450 protein family on drug metabolism on the optimum dose of each drug for different individuals.

Phenotype The observable characteristics of an organism. These may be structural, functional, or (with higher animals, particularly man) behavioral, and they derive from both the organism's genetics and its environment.

Phosphorylation Generally, the addition of a phosphate (PO3-) group to any (usually organic) molecule. In proteomics, the addition of a phosphate group to the hydroxyl group of a serine, threonine or tyrosine residue of a protein. Protein phosphorylation is controlled by the large kinase family of enzymes and is extremely important in cellular signaling pathways.

Phylogenetic Footprinting A bioinformatics technique for identifying regulatory elements in DNA by locating regions of orthologous noncoding DNA that show unexpectedly high conservation between species.

Phylogenetic Marker A gene, coding for either RNA or protein, that can be used for phylogenetic analysis because changes in its sequence can be consistently followed throughout a relevant period of evolutionary history. Genes that are highly conserved throughout long evolutionary distances, such as RNA genes and certain essential proteins such as vacuolar ATPases (ubiquitous in eukaryotes) and cytochromes, are commonly used as phylogenetic markers.

Phylogenetic Profile A binomial string that describes the presence or absence of a particular gene in all fully sequenced genomes – thus, if a gene is present in a species' genome a "1" will be entered in that position in the string, whereas if it is not, a "0" will be entered. As proteins that take part in, for instance, the same metabolic pathway or process are likely to evolve in a correlated fashion, proteins with similar phylogenetic profiles are thought likely to be functionally related.

Phylogenetic Tree A tree diagram showing the evolutionary relationships between species, or between genes or proteins in a family, that are believed to have a common ancestor. The edge lengths of the "branches" correspond to estimates of the distance between the entities in evolutionary time. In a rooted tree, there is a unique node at the bottom of the tree that represents the (putative) most recent common ancestor of the entities at the "leaves".

Phylogenomics The use of molecular evolution (phylogeny) to help deduce the function of proteins. These techniques rely on the fact that genes that have diverged in speciation events (orthologs, e.g., human hemoglobin and mouse hemoglobin) are generally closer in function than genes that have diverged in duplication events (paralogs, e.g., human hemoglobin and human myoglobin). Phylogenetic analysis is used to deduce orthologs of genes of unknown function and information from those used in the annotation of the new genome.

pI *See* Isoelectric Point

Plasmid A piece of closed, circular, autonomously replicated, double-stranded DNA. Plasmids range in size between 1 and >200 kb. They are found mainly in bacterial cells, with copy numbers from one to several hundred per cell. They are one of the main means of horizontal gene transfer (and so the transfer of traits such as antibiotic resistance) between prokaryotes; modified plasmids are used in the construction of cloning vectors. In eukaryotes, plasmids may be found in mitochondria and plastids.
Source: Kahl, G, The Dictionary of Gene Technology (2nd Edition).

Pleiotropic A gene is defined as pleiotropic if mutations in that gene have different clinical effects. For example, mutations in the gene for fibrillin-1, located on human chromosome 15, cause Marfan syndrome, but that syndrome may bave strikingly different clinical effects, involving one or more of the skeletal, ocular, and cardiovascular systems. The fibrillin-1 gene is therefore described as strongly pleiotropic. The disease or condition concerned (in this case Marfan syndrome) may also be described as pleiotropic.

Poisson Distribution A probabilistic distribution used in statistical analysis to predict the likelihood of success of a trial in situations in which a large number of trials have been conducted but the probability of success in each individual trial is small. In bioinformatics, it can be applied, for example, to the probability of two sequences chosen at random having a similarity score similar to one that could be expected with sequences that have a common ancestor.

Polarity The phenomenon in which a nonsense mutation introduced into a gene transcribed early in an operon has the secondary effect of repressing expression of nonmutated genes downstream of the mutated gene. The mutation involved is termed a polar mutation or dual effect mutation.
Source: Kahl, G, The Dictionary of Gene Technology, 2nd edition (Wiley-VCH, 2001).

Poly-A Tail A sequence of 60–200 adenine nucleotides added to the 3′ end of most eukaryotic mRNAs after transcription by a template-independent poly(A) polymerase. Its role is to add stability to the mRNA.
Source: Kahl, G, A Dictionary of Gene Technology (Wiley-VCH, 2001).

Polycistronic An mRNA is said to be polycistronic if it contains the transcript of more than one gene, expressed under the control of a single set of transcription factors. Generally, a polycistronic mRNA will contain the transcripts expressed from a single operon (an example being the lac operon in *E. coli*). Most often, the proteins are synthesized separately, but sometimes the entire message will be transcribed into a polyprotein.

Polymerase Chain Reaction A technique used for the selective amplification of a region of target DNA between two annealed primers, by the DNA polymerase-driven extension of those primers in the 5′ to 3′ direction. It initially uses target DNA as the sequence template. The target DNA is first heated with an excess of primers, nucleotides, and DNA polymerase to over 93°C to separate the strands. It is then cooled, and the primers anneal to the original DNA. When the temperature is raised again, the polymerase catalyzes the extension of the primer strands. This produces two new duplexes and the cycle then repeats with the system being heated again to break the hydrogen bonds in the new duplexes.
Source: Savva, R, Techniques in Structural Molecular Biology (Birkbeck College Advanced Certificate) section 4: DNA Technology.

Polymorphism Any specific change in a DNA sequence that is found in some individuals, leading to heterogenicity in a population. This change in genotype may or may not lead to a change in phenotype. Polymporphisms may be in coding or noncoding DNA and may consist of deletions, insertions, inversions, genetic rearrangements, or single base changes. The last named are known as Single Nucleotide Polymorphisms or SNPs.

Polyphyletic In phylogeny, a taxonomic group is defined to be polyphyletic if it is not monophyletic or paraphyletic. A monophyletic group (or clade) consists of a single organism plus all its descendents; a paraphyletic group is a monophyletic group minus one or more distinct subclades. All other groupings (polyphyletic groups) are considered to be unnatural assemblages and are not used in phylogeny, even if there is a phenotype common to the organisms. An example of a polyphyletic group is the group of warm-blooded animals (mammals + bird).

Polyplex A complex formed between cationic polymers and DNA, used in nonviral vectors for gene therapy. Complexes formed by cationic lipids for the same reason are termed lipoplexes. The DNA in both these types of complexes is protected from degradation by nucleases. The linear polymer poly-L-lysine was the first cationic polymer to be used in this type of gene delivery, in 1998.

Polytopic Membrane proteins that are embedded in a cell or organelle membrane, that is, that cross the membrane more than once, and in contrast to single-term

membrane proteins. The term is usually reserved for the alpha-helical type of membrane proteins, which are not found in the outer membranes of Gram negative bacteria.

Population Isolate A population, generally of humans but potentially of other species that has been genetically isolated by geography and lack of outbreeding and that will therefore exhibit less genetic heterogeneity and a higher degree of linkage disequilibrium. Population isolates are very useful for the study of genetic diseases, as mutations may accumulate leading to unusually high prevalence of certain genetic diseases.

Population Structure In population genetics, a population has a structure if its distribution of genetic material is nonrandom. If population structure is undetected, genetic association studies can give both false-positive and false-negative results. Studies of common, multigenic disorders are particularly prone to this problem.

Position-specific Iterative BLAST *See* PSI-BLAST

Position-specific Scoring Matrix A matrix of numbers representing the likelihood of finding a particular base or amino acid at each position of a domain or motif. Each row of the matrix represents a base or amino acid type and each column represents a position in the motif or domain sequence, from the first to the last. The values in the matrix give the log odds of finding each residue at each position. These matrices are used to select regions that are similar to the sequence family modelled. In this method, gaps are not allowed in the motifs modeled.

Positional Cloning The cloning of a specific gene in the absence of a transcript or a protein product, using genetic markers tightly linked to the target gene and a direct or random chromosome walk by linking overlapping clones from a genomic library.
Source: Kahl, G, The Dictionary of Gene Technology, 2nd Edition (Wiley-VCH, 2001).

Positive Inside Rule A rule that states that the segments or loops of a polytopic membrane protein that lie inside the cell (i.e., in the cytoplasm) contain more positively charged residues than those that lie outside the cell, in the periplasm or the extracellular medium. It is often used with hydropathy analysis to predict the number, location and topology of helices in these proteins. TopPred and TMHMM are examples of publicly available algorithms that use this rule in their prediction of transmembrane helix topology.

Posterior Probability In Bayesian probability theory, the conditional probability of an event when empirical data has been taken into account. It may be calculated from the prior probability and the likelihood using Bayes' Theorem.

Posttranslational Modification Any chemical modification to a protein that is made once the protein has been transcribed from its mRNA. There are thought to

be several hundred different post-translational modifications, ranging from cross-linking with disulphide bonds and simple glycosylation and phosphorylation to the covalent binding of complex cofactors. The large number of posttranslational modifications in higher eukaryotes is one reason why their proteomes are much larger than their genomes.

Practical Extraction and Report Language *See* Perl

Preinitiation Complex Trivially, the protein–DNA complex that is assembled prior to the transcription of a gene. In practice, the assembly of all components of the basal transcriptional machinery – that is, the complex of universal nuclear proteins, comprising RNA polymerase II(B) and transcription factors – on the core promoter. The assembly of the preinitiation complex initiates transcription.
Source: Kahl, G, The Dictionary of Gene Technology.

Pre-mRNA Any complete primary transcript of a structural (protein-coding gene) before it is modified to form the mature transcript, which is, in turn, translated into protein. In eukaryotes, pre-mRNA includes transcripts of the exons as well as the introns. Spliceosomes – small organelles made up of protein and RNA – excise the introns and add new noncoding sequences to the 5′and 3′ ends of the DNA.

Premutation Allele An allele of a gene for one of the so-called triplet expansion diseases (e.g., Huntington's disease, Fragile X syndrome) that is toward the high end of the phenotypically normal range. Individuals carrying premutation alleles are at greatly increased risk of passing on a defective allele to their offspring as a result of further expansion. For example, individuals with normal alleles for Fragile X sydrome carry between 6 and 50 CGG repeats in that gene, individuals with premutation alleles between 50 and 200 repeats, and affected individuals often well over 200.

Prevalence The number, or percentage, of cases (generally but not necessarily of disease) present in a population at a given time. This is to be compared with the incidence of the disease, which is the rate of occurrence of new cases of the disease during a given period. A chronic and relatively benign disease such as asthma or arthritis will have a much greater prevalence than incidence.

Primary Structure The amino acid sequence of a protein. In practice, the term "primary structure" is only used as a synonym for sequence in structural proteomics, where it is viewed as the first grouping in the hierarchy of protein structure classification, coming before secondary structure (alpha helices and beta strands), tertiary structure (the fold of a single polypeptide chain) and quaternary structure (the arrangement of chains to form a functional protein).

Primer A short, generally synthetic oligonucleotide that is complementary to part of a larger DNA molecule. Primers form the 3′ end of substrates onto which DNA polymerases can add nucleotides to grow a new DNA chain. Primers are used

as templates in the polymerase chain reaction, and so must be chosen carefully if only the correct sequence of DNA is to be amplified.

Proband *See* Index Case

Profile A way of representing a multiple sequence alignment numerically as a matrix of scores, where each score represents the probability of finding a particular amino acid (or base) at a particular position in the profile. Profiles are often used for classifying protein domains into functional families; they can be used to model DNA sequence alignments, but this is much less common. Some databases, such as Pfam and Smart, use profiles generated using hidden Markov models.

Promoter A region of DNA located upstream of the initiation site, to which RNA polymerase binds to initiate transcription. The sequences of prokaryotic promoters, and of eukaryotic promoters that bind different types of RNA polymerase, have very different sequences. Promoter sequences of a particular type have quite divergent sequences but are characterized by specific short sequence patterns: for example, prokaryotic promoters have the so-called "Pribnow box" sequence at approximately position −10 and eukaryotic promoters that bind RNA polymerase II have the "TATA box" sequence at approximately position −25.

Prophase In the cell cycle, the first phase of cell division during which DNA replication occurs and the chromosomes condense. By the end of prophase, the chromosome pairs are visible under the light microscope, with each pair of daughter chromosomes held together by the centromere. Details of the chromosomes, including abnormalities, can be viewed easily during prophase.

Protease An enzyme that breaks peptide bonds by hydrolysis, thus breaking a protein into peptides. Most proteases are specific, that is, they only break bonds before and/or after particular patterns of amino acids. They have been divided into four main families based on the functional groups in their active sites: the aspartic (or acid) proteases, cysteine proteases, serine proteases, and zinc (or metallo-) proteases. In proteomics, proteases are used to break separated proteins into peptides prior to identification.

Protein Blotting *See* Western Blotting

Protein Fold, Fold Family *See* Fold

Protein Interaction Map A map showing the complex network of interactions between (preferably) a large subset of the proteins expressed in a given cell type at a given time. Protein interaction maps may be generated using two-hybrid technology.
Source: Kahl, G, The Dictionary of Gene Technology.

Protein Microarray An array of probes that is used, by analogy with cDNA microarrays, to determine which proteins are present in a sample. A signal is

detected whenever a protein binds to a probe (which may be, for example, an antibody). Protein microarrays much less advanced, technologically, than cDNA microarrays, but they are now becoming more available.

Protein Profiling Any technology that is used to quantify the expression level of every protein in a tissue sample may be described as a protein profiling technology. It is, essentially, the equivalent in proteomics of the DNA microarray in transcriptomics. The technologies involved are still very much in development but some of the most promising developments involve arrays of spotted antibodies or spotted protein antigens.

Protein–protein Interaction Map *See* Protein Interaction Map

Protein Sequence-structure Space *See* Sequence-Structure Space

Protein Trafficking The processes by which proteins synthesized in a cell nucleus move through a cell to their eventual destinations – within the cytoplasm or an organelle, embedded in a cell or organelle membrane, or secreted from the cell – are generically known as protein trafficking. The endoplasmic reticulum and Golgi bodies are involved in trafficking. Some parts of protein sequences, such as signal peptides, may determine protein location.

Proteinase, Peptidase *See* Protease

Proteoglycan A particular type of glycoprotein (or protein-saccharide conjugate) that is heavily glycosylated, that is, has a high proportion by mass of saccharide. Proteoglycans always consist of a core peptide chain with one or more linear chains of glycosaminoglycans that have sulphate and/or urate groups attached and so are negatively charged. Proteoglycans can have a variety of forms and functions.

Proteolysis The breakdown of a protein into peptides by a protease. There are hundreds of different proteases known, each with a different specificity. In complete proteolysis the protein is broken down into its constituent amino acids. Proteolysis is a natural function that occurs in all organisms, even viruses, but it is also an important part of many scientific analyses. In core proteomics methodologies, separated proteins are broken down into short peptides by proteolysis before mass analysis. Trypsin is one enzyme that is very commonly used for this.

Proteolytic Peptide Peptides that are produced from the digestion of a protein by a protease trypsin are termed proteolytic peptides. The digestion of proteins into fragments, using proteases – most often trypsin (hence tryptic peptide) – is the first step in the procedure of protein identification using mass spectrometry. Trypsin cleaves preferentially after the positively charged amino acids lysine and arginine.

Proteolytic Processing *See* Proteolysis

Provirus Any viral DNA that becomes an integral part of the host cell chromosome and is therefore transmitted from one cell generation to another without lysis of the host cell. A retrovirus that has been integrated into a host chromosome is an example of a provirus. Similarly, a prophage is bacteriophage DNA that becomes integrated into the chromosomal DNA of a bacterial host.
Source: Kahl, G, The Dictionary of Gene Technology.

Pseudogene A nonfunctional derivative of a functional gene that has been inherited by an organism but is no longer needed. During evolutionary history, the sequences of pseudogenes mutate to prevent normal gene expression, for example, by changing promoter region sequences or inserting stop codons. Pseudogenes often retain significant similarity to functional genes in other species and so may be found by homology-based gene finding programs.

Pseudoknot A complex structural interaction between local regions of an mRNA molecule in which one strand of an RNA hairpin is folded back on itself to form, first, a second loop and then a series of base pairs with bases in the loop region of the first hairpin.

PSI-BLAST A form of BLAST in which the database is searched with a profile of sequences rather than a single sequence. The first cycle of PSI-BLAST is a traditional BLAST run; then a profile is constructed from the sequences that match the first sequence and a second cycle of BLAST run using that profile. The process is then repeated until no further sequences are added in a run, at which point the run is said to have conserved. PSI-BLAST can only be run with protein sequences. It is a sensitive method of finding distant homologs.

PSSM, Weight Matrix *See* Position-specific Scoring Matrix

QTL *See* Quantitative Trait Locus

Quadrupole Ion Trap A type of mass spectrometer that has been developed relatively recently and which is both sensitive and versatile. Ions are focused into the ion trap machine using electrodes, and the ions are injected into the trap using an electrostatic ion gate, which pulses open and closed. The ion trap is filled with helium. The kinetic energy of the ions is reduced by collisions with helium atoms, and the ions are trapped with their movement depending on their mass and charge. This allows the precise determination of mass/charge ratios.

Quantitative Trait Locus A genomic region that contains two or more genes or two or more separate genetic loci (map positions) that are known to contribute cooperatively to the establishment of a specific phenotype or trait.
Source: Kahl, G, The Dictionary of Gene Technology.

Quaternary Structure The highest level in the hierarchy of protein structure. Quaternary structure describes the association of more than one separate protein chain into an active protein complex, held together by disulfide bonds or

noncovalent interactions. The association of the four globin chains that make up hemoglobin is a simple example.

Radiation Hybrid Map A dense map of a mammalian chromosome that is created with a somatic cell hybrid technique. Pairs of genes are localized by using two gene-specific primers to amplify a single PCR product, which is then given a radioactive label and hybridized to a panel of radiation hybrid clones. Hybridization indicates that sequences complementary to the PCR product are present in a radiation hybrid clone.

Ramachandran Diagram *See* Ramachandran Plot

Ramachandran Plot A plot of the two torsion angles that, between them, describe the backbone conformation of an amino acid within a protein against each other. Generally phi, the torsion angle about the N–CA bond, is plotted on the x axis and psi, the torsion angle about the CA–C bond, on the y axis. Each amino acid will therefore be represented by a single point. The positions that may be adopted in real proteins are limited by steric hindrance to regions corresponding to alpha helices and beta strands, and a smaller, less populated region corresponding to the left-handed alpha helix.

Read Length The length (in bases) of the small pieces of DNA that are sequenced using Sanger's sequencing techniques and then assembled into longer pieces (and eventually into chromosome and genome sequences) is termed the read length. Computer programs are used to assemble the resulting short sequences. A typical read length in many sequencing projects is 500 bases.

Reading Frame The position from which the codons defining amino acids are read when a DNA sequence is translated into protein. As codons contain three bases, each strand may be read in three ways, so, for instance, a sequence beginning ACGT . . . may be read starting from the A, the C and the G; if the sequence starts from the T, it is read in the first reading frame with the first codon (amino acid) missing. Any gene sequence may be read in six reading frames, three on the forward strand and three on the reverse strand.

Real Time PCR A method of monitoring the amount of a gene produced during the polymerase chain reaction (PCR) using a fluorescent reporter. The amount of fluorescence, which can be measured directly in real time, is directly dependent on the amount of reporter and thus on the amount of amplicon present. It can thus be used throughout the PCR reaction, including the exponential phase, and not just at the end. Real time PCR is sensitive, specific, and reproducible over a wide range of concentration ranges.

Receptor A protein that recognizes another molecule (known as its ligand) and becomes activated when that ligand binds. This activity may take one of a number of forms, including, for instance, conformational changes and binding further molecules. The genomes of free-living organisms contain genes for many hundreds,

if not thousands, of different receptors. They are probably the most important large family of protein drug targets. Drugs targeted at receptors may duplicate the receptor activity (agonists) or block the receptor site preventing activity (antagonists).

Recessive A recessive trait or phenotype is one that is not expressed unless an individual carries two alleles for that trait. Many genetic conditions, including the relatively common cystic fibrosis, are inherited as recessive traits. The existence of dominant and recessive traits was one of the key discoveries of Gregor Mendel, which led to the invention of genetic mapping. It is now known to be an oversimplification.

Recombination Hot Spot The rate of recombination is the rate at which genes are combined in a "child" cell or organism in a different pattern from that in which they are found in either of the parents, for example, due to exchange of DNA between chromosomes. The rate of recombination is not constant throughout a genome, or even an individual chromosome: areas of the genome where recombination is particularly common are known as recombination hot spots. (Similarly, regions where recombination rates are low are known as cold spots.)

Redundancy Generally, a code is said to be redundant if part of it is unnecessary because more than one entity in the code maps on to the same entity in the translation. In molecular biology and bioinformatics, the genetic code is said to be redundant because 64 different codons code for 20 amino acids plus the stop signal. The number of codons that code for individual amino acids ranges between one and six.

Reflectron A mass analyzer, used in mass spectrometry and thence in proteomics, that focuses a beam of ions by reversing the direction of the ions using a retarding electric field. The result is a reduction in the spread of kinetic energies in the ion beam. Types of reflectrons available include single-stage (the simplest), dual-stage, quadratic, and curved-field.

Regular Expression An expression of characters, normally alphanumerics and symbols, that can be matched automatically using pattern matching software. Regular expression matching is commonly used in bioinformatics algorithms, in, for example, searching for amino acid or base patterns. The Unix tools sed, awk, and grep use regular expression matching and the programming language Perl has been optimized for this programming task.

Regulator A gene coding for a protein, known as a repressor, that blocks the activity (DNA binding) of an operator and so prevents transcription of the adjacent operon. In these cases, transcription is often induced by effectors that bind to the repressor proteins, causing changes to the repressor structure and preventing its binding.
Source: Kahl, G, The Dictionary of Gene Technology (2nd edition).

Regulator Gene *See* Regulator

Regulatory Network A network of interactions between genes in which the condition represented by the edges is regulation; that is, two genes (nodes) are joined by an edge if the expression of one regulates the expression of the other. It is self-evident that all regulatory networks are directional.

Relational Database Any database that is built using the relational model is termed a relational database; the best-known commercial example is probably Oracle. A relational model is a logical data structure defined using set theory, so each data item is a member of one or (usually) many more than one set. It can be stated more simply by saying that the data is collected in tables that are linked using keys, so relationships may be modeled across tables.

Replication Competent Simply, a piece of DNA that is able to replicate is replication competent (the opposite being replication deficient). The term is often used in virology and gene therapy; a virus vector for gene therapy that is replication competent will be able to multiply and distribute the introduced gene round the body.

Replication Fork Trivially, a region of genome sequence that starts with an initiation (START) codon and ends with a termination (STOP) codon, and so is translated into protein. A scan of a genome sequence for long ORFs is the first and easiest stage of gene prediction. In practice, the situation is much easier in prokaryotic genomes than in eukaryotic genomes, which are complicated by the extreme length of some genes, the presence of introns, and the necessity of identifying splice sites.

Replicon A segment of DNA under the control of a single replication-initiation locus and behaving as an autonomous unit during DNA replication. Whole plasmids and bacterial chromosomes are replicons. In eukaryotes, the number of replicons tends to increase with increasing genome size and organism complexity (e.g., yeast: 500 replicons, average size 40 kb; mouse: 25 000 replicons, average size 150 kb).
Source: Kahl, G, The Dictionary of Gene Technology (2nd edition).

Reporter Gene A network of interactions between genes in which the condition represented by the edges is regulation; that is, two genes (nodes) are joined by an edge if the expression of one regulates the expression of the other. It is self-evident that all regulatory networks are directional.

Repressor A protein that binds specifically to the regulatory sequence of an operator gene, blocking the movement of the RNA polymerase along the operator DNA and therefore blocking the initation of transcription. The affinity of repressor proteins can be modulated by small molecules that are known as effectors. Many repressors use the helix-turn-helix motif for binding the operator DNA.

Restriction Endonuclease *See* Restriction Enzyme

Restriction Enzyme An enzyme that recognizes specific short target sequences in double-stranded DNA and catalyzes the formation of double-strand breaks.

Restriction enzymes are natural enzymes that protect cells from foreign DNA, and are frequently used in molecular biology. Many different restriction enzymes that are known to recognize different oligonucleotides are used to detect small differences between DNA sequences.

Restriction Fragment Length Polymorphism A polymorphism in which different alleles have different sequences at one or more restriction enzyme cut sits, so that in at least one case, a cut site is added or removed. Cutting the gene sequence using the restriction enzyme concerned will therefore produce fragments of different lengths that can be easily identified. This is a simple and cost-effective way of detecting polymorphisms.

Retrovirus A member of a class of viruses that infect eukaryotic cells and that has single-stranded RNA as its genetic material. After the virus infects a cell, its RNA is reverse-transcribed into a copy of the eukaryotic DNA by the enzyme reverse transcriptase; the integrated (endogenous) retrovirus is termed a provirus. When the endogenous retrovirus is transcribed viral proteins that can associate into new virus particles are formed. Human immunodeficiency virus (HIV), which causes AIDS, is the best known retrovirus.

Reverse Transcription The process, catalyzed by the enzyme reverse transcriptase, by which a double-stranded DNA molecule is transcribed using a single-stranded RNA molecule as a template and a primer. Reverse transposition is used in recombinant DNA technology for the synthesis of cDNA from messenger RNA. It is also the process by which retrovirus DNA is integrated into the eukaryotic genome.

RFLP *See* Restriction Fragment Length Polymorphism

RH Map *See* Radiation Hybrid Map

Risk Factor Any feature that is known to increase a person's chance of developing a disease is termed a risk factor. Risk factors may be lifestyle related (e.g., smoking, obesity, sun exposure) or genetic; well-known examples of the latter are the defective alleles of the BRCA1 and BRCA2 genes, which convey a greatly enhanced risk of developing breast or ovarian cancer.

RMSD *See* Root Mean Square Deviation

RNA Interference The silencing of a specific gene (i.e., the blocking of gene expression) by micro-injection single- or double-stranded RNA that is complementary to the gene to be silenced into cells. It is used in comparative genomics for determining the function of a gene. The injected RNA may in some circumstances be transmitted to germline cells and observed in the experimental organism's progeny. RNA interference is also a natural mechanism for silencing gene expression.

RNAi *See* RNA Interference

Robustness A bioinformatics method or algorithm is described as robust if is reliable and both sensitive and specific, that is, if it predicts features (for example) with few false positives and false negatives. Signals within sequences, defined as patterns or profiles, can also be defined as robust if they predict family members with great accuracy. Generally, increasing the number of sequences that contribute to a pattern or profile will increase its robustness.

Root Mean Square Deviation A measure of the similarity of two structures as the square root of the mean of the squares of the (scalar) distances between selected points. In an analysis of protein structures, the points chosen are self-evidently the atoms; generally, only main chain or alpha-carbon atoms are used. The root mean squared deviation between a model protein structure and the experimentally determined structure of the same protein is a very useful measure of the quality of the prediction; a good model based on a close homolog may have a RMSD of less than 1 Angstrom from the experimental structure.

Rotamer The side chains of amino acids in protein structures are restricted by steric hindrance and therefore preferentially take up certain conformations, which are known as rotamers. Libraries of rotamer conformations are included in programs for three-dimensional protein structure determination and homology modeling, where they are used to suggest likely side chain positions.

RT-PCR *See* Real Time PCR

S-nitrosylation A posttranslational modification of cysteine residues in proteins, involving the addition of a nitro group to the free thiol. Like phosphorylation, it is thought to represent a mechanism for reversible posttranslational regulation of protein activity and consequently of cellular function.

SA *See* Structured Association

SAGE *See* Serial Analysis of Gene Expression

Scale free A network can be described as scale free if the number of connections at each node is distributed very unevenly, that is, if there are a small number of very highly connected nodes. In these networks, the probability that a given node is connected by a given number of connections is determined by a power law. The highly connected nodes are termed the hubs of the network. Many examples of scale free networks can be taken from bioinformatics and other disciplines. Gene networks can be scale free if they contain genes with particularly high numbers of connections.

Schema A term used in several disciplines within computer science to mean a model. For example, in database theory, the schema is the structure of the database,

and in XML, the XML schema defines the structure of the XML documents. The term may also be used to mean a specialized type of ontology.

ScRNA The RNA component of small cytoplasmic nucleoproteins (scRNPs), which are found in the cytoplasm of eukaryotic cells. These scRNPs are RNA-protein complexes that are involved in the splicing of nuclear percursor RNA after its transport into the cytoplasm. They are released from the mRNA before it is translated into protein.
Source: Kahl, G, The Dictionary of Gene Technology.

SDS-PAGE The most commonly used method for separating proteins by molecular mass; one of the two methods routinely used in two-dimensional protein separation. The protein mixture is loaded with a detergent, most often sodium dodecyl sulphate (SDS); this denatures them and confers a negative charge that is proportional to their molecular mass. Migration of SDS-protein complexes on polyacrylamide gels will therefore depend largely on molecular mass.

Second Messenger A signal transduction protein is termed a second messenger if it passes a signal on; that is, second messengers relay signals received by cells following the activation of cell surface receptors to their target molecules. Second messengers also amplify the strength of the signal received. There are three main classes of second messenger: cyclic nucleotides, inositol triphosphate and diacyl glycerol, and calcium ions.

Secondary Structure The second level in the hierarchy of protein structure, describing short stretches of the polypeptide chain that have regular backbone geometry and patterns of main chain–main chain hydrogen bonding. There are two common types of secondary structure, the alpha helix and the beta strand: beta strands associate into sheets, and these sheets – and certain types of tight turn between beta strands – are sometimes included in this structural category.

Segmental Duplication A duplication of a relatively large segment of DNA within a genome sequence is termed a segmental duplication. A high degree of sequence identity within the duplicate regions indicates that the duplication event occurred relatively recently in evolutionary history. The human segmental duplication database contains all duplicates that are greater than 1kb in length and share greater than 90% sequence identity.

Segregation The process by which chromosomes separate during meiosis and mitosis and migrate toward opposite ends of the cell is termed segregation. Segregation occurs during late metaphase and anaphase; the daughter chromosomes are drawn toward the ends of the cell by the microtubules.

Selective Pressure Any change in the environment of a species that leads to some variants being more favored than others, and which therefore leads to those variants surviving and reproducing in greater numbers, is a selective pressure on that species. A classic example, often described in elementary texts, is the rise in

pollution during the Industrial Revolution, which increased the chances of survival of dark pigmented moths.

Selective Sweep An evolutionary event in which a favourable mutation is incorporated into the genome of a species so that it becomes the dominant variant so quickly that alleles that are linked to that mutation also become incorporated into the genome. It can therefore be difficult to identify the allele that is the original target of the selective sweep. The linked genes can be said to have been "hitch-hiked" into the genome.

Selectivity A value that indicates how successful a test is in selecting mismatches (=negatives) from a sample set. It is calculated as the ratio of true negatives (TN; samples that do not have the feature tested for and also fail the test) to all those that do not have the feature (false positives and true negatives); thus specificity = TN/(TN+FP). Specificity ranges between 0 and 1; a perfect test will have a specificity of 1.

Sensitivity A value that indicates how successful a test is in selecting matches (=positives) from a sample set. It is calculated as the ratio of true positives (TP; samples that have the feature tested for and also pass the test) to all those that have the feature (true positives and false negatives); thus sensitivity = TP/(TP+FN). Sensitivity ranges between 0 and 1; a perfect test will have a sensitivity of 1.

Separation Matrix In proteomics experiments, the first step is very often the separation of a protein mixture by mass and/or charge. The protein sample must be dissolved in a compound, such as a gel, before separation can take place; this is the separation matrix. Polyacrylamide is most commonly used (hence the term 2D-PAGE, or 2-G polyacrylamide gel electrophoresis) but others, including polyethylene oxide and hydroxycellulose, have also been used.

Sequence Gap *See* Sequence-Structure Gap

Sequence Profile *See* Profile

Sequence Signature A pattern of residues within a protein that is associated with, for example, a particular functionality or a type of posttranslational modification. Sequence signatures may be long or short, simple or complex, and based on regular expressions, weight matrices, profiles or hidden Markov models. There are many databases containing information on sequence signatures, some of the best known being PROSITE, Pfam, Prints and Smart, and there is one meta-database, Interpro, that collects together information from these and other source databases.

Sequence-structure Alignment The alignment of the sequence of one protein with the structure of another, which may be either homologous or analogous. Sequence-structure alignment is computationally a much harder technique than sequence–sequence alignment. This method is used prior to protein structure

prediction only when no structures of proteins that are clearly recognizable as homologs at the sequence level are available.

Sequence-structure Gap The gap between the number of proteins of known sequence and the number of proteins of known structure, that is, the number of known proteins with no experimentally determined tertiary structure. This gap is still growing, as the structure determination is not keeping place with the number of translated gene sequences coming out of genome projects. It can be narrowed by using homology modeling to predict the structures of proteins that are homologous to proteins of known structure.

Sequence-structure Space A conceptual term used to describe the complete range of protein sequences and structures that have been generated by evolution. Structural proteomics (or structural genomics) program that aim to find unknown folds or solve the structures of unknown sequences without taking much account of the known or predicted function of the proteins are described as searching or filling protein sequence-structure space.

Sequence Tag *See* Peptide Sequence Tag

Serial Analysis of Gene Expression A high-throughput technique for the simultaneous detection and analysis of almost all the genes that are expressed in a given cell at a given time. It is based on the isolation of a short sequence tag, a so-called “SAGE tag” or “diagnostic tag” , from a defined location within the transcript. This tag contains sufficient sequence information to uniquely identify the transcript. The tags are concatenated into a single DNA molecule for sequencing, which aids rapid identification of the tags and therefore the genes from which they are derived. The software used for gene identification with SAGE is also able to determine expression levels.
Source: Kahl, G, The Dictionary of Gene Technology, 2nd edition (Wiley-VCH, 2001).

Short Tandem Repeat, STR *See* Microsatellite

Shotgun Sequencing The determination of the sequence of bases in a complete genome by a method that involves the fragmentation of the target genome or its chromosomes by physical or enzymatic means, the cloning and sequencing of the resulting fragments and the reconstruction of the complete sequence by ordering the fragments. It was used in the publicly funded Human Genome Project.
Source: Kahl, G, A Dictionary of Gene Technology.

Side Chain The part of an amino acid within a protein that is covalently bonded to the alpha carbon atom and, therefore, not part of the continuous main chain of the protein. The genetic code can code for 20 amino acids with different side chains; some other variants can be created by posttranslational modification. The chemical nature of amino acid side chains determines the biochemical properties of the amino acids and, thence, the function of the proteins that they are built from.

Signal Peptide A sequence of generally 15–30 mainly hydrophobic residues at the N-terminal end of a protein. Its function is to target the protein to, and then across, the cell membrane. The protein will then be cleaved at the end of the signal peptide, releasing the mature protein from the cell. There are often positive charges at the far N-terminus of the sequence and negative ones just C-terminal of the cleavage site. Many reliable programs for the recognition of signal peptides and consequent prediction of cellular location are available.

Signal Sequence, Leader Peptide *See* Signal Peptide

Signal Transduction *See* Transduction

Silent gene *See* Pseudogene

Similarity Search A general term for a program for searching a DNA or protein sequence database for sequences that are similar to a test sequence, such as BLAST or FastA. Similarity searches are often termed homology searches, but this is a misnomer: the programs do not explicitly determine homology and this must be inferred by the expert user. There is always a "grey area" where sequence similarity may or may not be statistically significant.

Simulated Annealing A technique used in simulation of macromolecular (or any molecular) structure in which the molecule is "heated up" (i.e., its kinetic energy is increased) during a molecular dynamics simulation. The increase in kinetic energy allows the structure to cross energy barriers. The temperature is then reduced to more physiologically appropriate ones. Repeated simulated annealing experiments allow the molecule to sample more of the available conformational space, increasing the chances of approaching the global energy minimum for the structure.

Single Nucleotide Polymorphism Strictly, a type of polymorphism in which there is a base change at a single position only (e.g., a single A is changed into T, C, or G with the surrounding sequence left unchanged). SNPs occur in coding and noncoding regions, and coding SNPs may be silent (i.e., the codon change does not affect the coded amino acid). Sometimes, small insertions and deletions are included in the same category as SNPs. There are estimated to be 3–30 million SNPs in the human genome.

Single Transmembrane Segment *See* Membrane Anchor

Site-directed Mutagenesis A technique for introducing single amino acid changes into a protein by making specific changes to single base pairs at specific sites in a target DNA. Often used to probe the effects of small changes on the structure or function of a protein.

Small Cytoplasmic RNA *See* ScRNA

Small Nuclear RNA *See* snRNA

Small Nucleolar RNA *See* snoRNA

Smith–Waterman Algorithm A dynamic programming method of aligning pairs of sequences that was adapted from the Needleman–Wunsch method to produce local alignments between the whole sequences. The output will be one or more high scoring sequence segments, with or without internal gaps; gaps at the end of sequences will be removed. The order of matching regions may differ between the sequences. Local alignments and methods that depend on them are often used to identify conserved domains. This method is used in, for example, the EMBOSS local alignment program, WATER.

snoRNA A class of small RNA molecules that are involved in chemical modifications of other RNA genes. They are a component of the small nucleolar ribonucleoprotein complex (snoRNP), which also contains protein. The snoRNA guides the snoRNP complex to the modification site of the target RNA gene via snoRNA sequences that hybridize to the target site.

SNP *See* Single Nucleotide Polymorphism

snRNA An abundant class of relatively small, uridine rich RNA molecules, 100–300 nucleotides in length, which are associated with small nuclear ribonucleoprotein particles. These are found in the nucleus and needed for RNA splicing. The U-RNA family is a strongly conserved family of snRNAs, and its members are designated U1-U10.
Source: Kahl, G, The Dictionary of Gene Technology.

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis *See* SDS-PAGE

Solvent Accessible Surface In computer-based molecular modeling, a surface around a molecule that is created by virtually rolling a “probe” , usually the size of a water molecule, around the molecule in direct contact with it and plotting the trajectory of the center of the probe. It is larger and “smoother” surface than that built using atomic van der Waals radii and includes those parts of the molecule that are accessible to solvent.

Somatic Cell Any eukaryotic cell other than a germ cell – that is, any cell that is normally diploid. The term somatic gene therapy, or somatic gene therapy, is used for any process by which the genomes of somatic cells are artificially altered. This is safer than altering germ cells, and raises fewer ethical questions, as the germline of the individual is not altered.

Southern Blotting A well-known method for the detection of specific DNA fragments. The DNA fragments are first separated using agarose gel electrophoresis; then the separated fragments are blotted onto nitrocellulose paper. Labeled cDNA probes are hybridised onto the separated bands, which can then be viewed using autoradiography. The similar technique of Northern blotting is used to detect sequences in RNA.

Space Charge Effect An effect that limits the current in a beam of ions of like charge, such as that in a mass spectrometer, arising from mutual repulsion between the ions. Space charge is a consequence of Coulomb's Law, which states the repulsion between particles of like electrostatic charge. In practice, the space charge effect leads to an expansion in radius of the charged ion beam.

Speciation The evolutionary process by which a branch of the Tree of Life bifurcates to form two distinct species. A species is defined as a population of individual organisms that share extremely similar phenotypes and genetic makeup. Where sexual reproduction occurs, male and female individuals of the same species must be able to produce fertile offspring. In prokaryotes, the basic definition of speciation is confused by horizontal gene transfer.

Specificity Window Many procedures in sequence analysis (e.g., hydropathy profiles, dotplots) involve defining a stretch of contiguous residues, calculating a given property and then recalculating the same property for each stretch of residues along the entire sequence. This is known as defining a "window" that is "slid" along the sequence.

Spike-in Control, External Standard, Exogenous Control *See* External Spike-in Control

Splice Acceptor Element A segment of DNA that, if included in a vector upstream of a gene sequence, will be read as a splice acceptor signal (intron–exon boundary) and thus enable that gene to be transcribed if it is inserted within an intron of a transcribed gene. Splice acceptor and donor elements are used, for example, in the technique of gene trap mutagenesis, in which mutated genes are inserted into the mouse germline.

Splice Acceptor Site/Splice Donor Site; Acceptor Splice Junction/Donor Splice Junction; other variants *See* Splice Site

Splice Donor Element A segment of DNA that, if included in a vector downstream of a gene sequence, will be read as a splice donor signal (exon–intron boundary). If a splice donor site is incorporated without a poly-A sequence the gene will only be transcribed if a poly-A signal can be obtained from the endogenous gene. Splice acceptor and donor elements are used, for example, in the technique of gene trap mutagenesis, in which mutated genes are inserted into the mouse germline.

Splice Site In eukaryotic genes containing introns, the junction between an exon and intron at the 3′ end of the intron (splice acceptor site) and the junction between the intron and the exon at the 5′ end of the intron (splice donor site). Both types of splice sites may be identified from consensus DNA sequences.

Spliced Alignment A method of gene finding from a DNA sequence and a set of candidate predicted exons, by searching the set of possible exon chains for the one with the best fit to a related protein sequence. The original exon set is constructed

by considering all possible donor and acceptor splice sites in the genomic sequence. Although this gives an enormous number of candidate exons, most of which will be false positives, the method can be very fast.

Statistical Overrepresentation If certain gene or protein sequence patterns are more frequently found in a longer sequence than they would statistically be expected to be, they are said to be statistically overrepresented in the longer sequence. The opposite phenomenon is termed statistical under-representation. Sequences that are overrepresented may be functionally important whereas underrepresentation indicates that that particular (possibly functional) motif may have deleterious consequences to the organism.

Stem Cells A type of cell that has the potential to differentiate into any one of many different types of cell. Stem cells potentially have very important applications in therapy, particularly for degenerative diseases. The most effective stem cells are embryonic stem cells, derived from early embryos, but the use of these is extremely controversial. Stem cells may also be derived from the umbilical cord or produced from certain types of ordinary cell using chemicals.

Stratification *See* Substructure

Stringency In general terms, the extent to which errors or mismatches are tolerated in a detection experiment or a bioinformatics calculation. Thus, in sequence analysis, stringency is used to set the number of mismatches allowable in a sequence segment defined as a hit (e.g., one that generates a dot in a dotplot). Similarly, a PCR reaction that is relatively tolerant of errors in the resulting sequences is defined as a low stringency reaction.

Structural Genomics *See* Structural Proteomics

Structural Proteomics Any experimental program for solving protein structures by X-ray crystallography or nuclear magnetic resonance that may be described as high throughput, aiming to solve a large number of different structures in a short time, may be termed a structural proteomics (or, confusingly, structural genomics) program. There are two main approaches: either experimentalists concentrate on solving proteins from a particular bacterium or involved in a particular disease, or they attempt to increase the coverage of sequence-structure space by picking proteins predicted to have unknown folds.

Structured Association A method of reducing the chance of finding spurious associations between genes and disease in the large populations that are necessary for the study of the genetics of complex diseases, caused by population heterogeneity. In structural association methods, the details of the population substructure are inferred during the early stages of association testing, so they can be taken into account during the rest of the analysis.

Subcellular Compartment In simple terms, a part of a cell, such as the nucleus, the cytoplasm, or the cell membrane. Bioinformatics tools may be used to predict,

with reasonable accuracy, the subcellular compartment or compartments in which a protein is most likely to be found: to take a simple example, proteins containing hydrophobic segments of a certain length are likely to be found embedded in the cell membrane.

Subgraph Graph theory is used in bioinformatics, for example, to analyze the expression patterns of a group of genes. In graph theory, “A subgraph of the graph G is defined as a graph whose vertex set is a subset of the vertex set of G, whose edge set is a subset of the edge set of G, and such that the map w is the restriction of the map from G.”

Substitution Matrix *See* Weight Matrix

Substructure The genetic heterogeneity in large populations that causes problems such as spurious association (false positives) in population-based studies of genetics of complex diseases is generally known as population substructure or stratification.

Supertree Phylogenetic trees of prokaryotic species based on single genes are limited by, among other factors, the amount of horizontal gene transfer between species. It is considered that phylogenetic trees derived from many genes or even whole genomes may reconstruct the prokaryotic “tree of life” more accurately. The supertree approach to combining phylogenetic information combines single-gene trees rather than sequence alignments. It can be used to combine trees that share only a few species, and it can be used where whole-genome sequences are not available for all species.

Synteny Regions of genomes (generally from quite closely related species) that share at least gene content and often gene order are said to exhibit synteny. Often gene order will be partly disrupted by gene loss, inversion and duplication events. In eukaryotic genomes, large chromosomal regions are conserved throughout chromosomal rearrangements, so regions of one chromosome will be syntenous with parts of different chromosome from related species.

Systems Biology Any one of a number of disparate techniques to study, and specifically to model using mathematics and engineering techniques, the various components of a biological system as the integrated system, for example, modeling a cell using its component molecules, or an organ or tissue using its component cells. It may also be thought of as a mathematical way of thinking of physiology.

Tag SNP Single nucleotide polymorphisms (SNPs) that are known to be associated with haplotype blocks (DNA segments located between recombination hot spots that are usually inherited as blocks). It is possible to genotype individuals for susceptibility to complex diseases using fewer SNPs in total if only the known tag SNPs are used.

Tandem Mass Spectrometry A method for separating and identifying proteins using mass spectrometry (MS) alone, without an initial electrophoresis step. It

uses two mass spectrometry steps, hence the term "tandem MS". The first MS step separates a single protein ion from a mixture. The second step fragments the protein into a series of peptides and analysis of the fragmentation pattern gives ride to short sequence fragments that can be used to identify the protein. Often, electrospray is used for the first ionisation: this technique is known as ESI-MS-MS.

Tandem Repeat In gene sequence analysis, the arrangement of two or more identical sequences within a DNA molecule so that they are close neighbors. These can either be direct (head-to-head) or indirect (head-to-tail), in which case one of the sequences is reversed. The term may also be used to refer to two or more chromosomal segments that are arranged as close neighbors within the chromosome.
Source: Kahl, G, The Dictionary of Gene Technology.

Taq Polymerase An enzyme (EC 2.7.7.7) from the thermophilic eubacterium *Thermus aquaticus* (strain YT 1 or BM), which polymerizes deoxynucleotides with little or no 3′-5′ or 5′-3′ exonuclease activity. It is thermostable (optimum temperature 70–75°C) and allows the selective amplification of any cloned DNA about 10 million-fold with high specificity and fidelity. It is also used to label DNA fragments with radioactive nucleotides, biotin or digoxygenin, and it can be used in Sanger sequencing.
Source: Kahl, G, The Dictionary of Gene Technology.

TATA Box An AT-rich DNA region with the consensus sequence TATAT/AAT/A (in plants, the consensus is TATAATA) most frequently located a few tens of base pairs upstream of the transcription initiation site of eukaryotic genes. It represents the transcription factor binding site; it is essential for accurate initiation of transcription, but not necessary for quantitative expression. It is not found in the promoters of most constitutively expressed ("housekeeping") genes.
Source: Kahl, G, The Dictionary of Gene Technology.

Taxon In phylogenetic analysis, each individual sequence (or species) represented in a phylogenetic tree is described as a taxon (plural: taxa). Each taxon is a phylogenetically distinct unit and appears on the tree as a point at the top level of the tree (so following the analogy further, the taxa are the leaves).

TCS *See* Tentative Consensus Sequence

TDT *See* Transmission-disequilibrium Test

Telomere The ends of eukaryotic chromosomes are known as telomeres. They are usually gene poor, and the telomere tips contain highly repetitive DNA sequences. Telomeres preserve the integrity of chromosomes during replication, and their length tends to decrease as the age of the organism increases. Telomere elongation is catalyzed by the enzyme telomerase.

Telophase The final phase of the cell cycle, during which nuclear membranes reform around each collection of daughter chromosomes and the cell divides in two.

In mitosis, the result is the division of the original cell into two identical daughter cells. Meiosis involves two cell divisions, resulting, after the second telophase, in four haploid gametes, each containing a single copy of each chromosome.

Tentative Consensus Sequence A consensus sequence of amino acids or (more often) of nucleotides which is inexact, that is, where not every position can be completely characterized. Tentative consensus sequences may, nevertheless, be used to search databases, using programs such as Scansite. Tentative consensus sequences are often used to characterise gene promoter regions.

Termination Site, Termination Sequence, Terminator Sequence *See* Terminator

Terminator Genome Sequencing

Tertiary Structure The structure or fold of a single protein (or polypeptide) chain and, originally, the third level in the hierarchy of protein structure, between secondary and quaternary structure. Now it is widely known that protein chains may fold into one or many domains and that each domain may be assigned to a different fold category. The terms “supersecondary structure” and “domain” have now been added to the structural hierarchy between the secondary and tertiary levels.

Tetraploidy A cell is defined as tetraploid if it contains four copies of each chromosome – that is, twice the genetic content of a normal diploid cell, or four times that of a haploid gamete. Mosaic tetraploidy (where only some cells are tetraploid) is quite common in preimplantation diagnosis but very rare in implanted embryos and fetuses. It is not clear whether this is because the condition is embryonic lethal or whether it is, in fact, harmless due to selective growthn of normal cells. Complete tetraploidy is known to be embryonic lethal.

Tetrasomy The presence of four chromosomes or part-chromosomes of the same type instead of two in a diploid genome. It arises following errors of segregation during meiosis. In humans, a full tetrasomy of a whole chromosome would be incompatible with life, but mosaic tetrasomies of part chromosomes (i.e., where the aberration occurs in some cells only) occasionally occur. A mosaic tetrasomy of chromosome 12p has been associated with profound mental retardation.

TF, Trans-acting Factor, Nuclear Factor *See* Transcription Factor

Thermus aqutaticus DNA Polymerase, Taquenase *See* Taq Polymerase

Threading A method for predicting the structure of a protein from its sequence in cases where no obviously homologous proteins of known structure are available. The test sequence is “threaded” through a variety of protein fold templates and the sequence-structure match evaluated using, for example, an energy function. David Jones’ THREADER is a good example of a public domain threading program.

Threshold In any analysis where data is to be classified into two (or more) groups, but where the programs used produce numerical scores, the threshold is the score that marks the boundary between two groups. The threshold is normally set by the user and its value determines the number of false negatives and false positives that the experiment will produce (if the threshold is set too low there will be many false positives; if too high, there will be many false negatives).

Threshold Score *See* Threshold

Time of Flight The most widely used type of mass analyzer in mass spectrometry, at least as that is applied to the identification of separated proteins. The peptide ions are accelerated so ions of like charge have the same kinetic energy; therefore, from basic physical principles, there will be an inverse relationship between the time taken for an ion to travel to the detector and its mass/charge ratio. This enables that mass/charge ratio to be determined as a step toward peptide and protein identification.

TOF *See* Time of Flight

Topology The arrangement and linking of a group of elements; the properties of a figure that are unchanged by continuous distortion (strict mathematical definition). In protein structure, the topology of a protein describes its overall shape and the connectivity between the elements; it is the term that is used to describe the third (Fold Family) level of the CATH protein structure classification. The term may also be used to describe the orientation of a transmembrane helix bundle in the membrane.
Source: Hancks, P, The Collins English Dictionary (Collins, 1986) for strict mathematical definition.

Torsion Angle *See* Dihedral Angle

Toxicogenomics The interaction between genomics and toxicology, or the influence that genetic variation has on drug toxicity. Common genetic variations (SNPs) may lead to drugs causing toxic side effects in some people. For example, drugs may accumulate to toxic levels in people with less efficient variants of enzymes in the cytochrome p450 family of metabolic enzymes.

Transactivation It often happens that transcription factor–DNA complexes must be stabilized by the binding of other proteins before mRNA transcription can take place. This stimulation of transcription by a transcription factor and its associated adjacent proteins binding to a promoter region is termed transactivation.

Transcript Capture A technique of measuring and identifying the mRNA content of a cell by harvesting (or capturing) the transcripts present in that cell before they can be degraded. This method can be used to monitor gene expression within and between cell types and to identify splice variants, including those resulting from exon-skipping events.

Transcription Factor A protein that binds to the recognition sequence of a DNA molecule, upstream of a coding sequence, and facilitates transcription initiation. DNA-dependent RNA polymerases bind to the transcription factor–DNA complex that activates RNA poymerization. Transcription factors may also bind to upstream regulatory sequences or even to sequences within the coding regions.

Transcription Profiling The use of microarray or similar technologies to determine a profile of the mRNA molecules (transcripts) present in a cell type under particular conditions and at a particular time. Very briefly, short pieces of cDNA molecules are immobilized on a grid, mRNA from the cell type under study is tagged with fluorescent probes and hybridized to the stationary cDNAs. Fluorescence at a spot indicates the presence of an mRNA that is complementary to that cDNA molecule.

Transcription Unit The complete DNA sequence between the transcription initiation site and the transcription termination site, both sites as recognized by the DNA-dependent RNA polymerase. A transcripton may contain one gene or more than one; in the latter case the message produced is polycistronic, but only in prokaryotes is this ever translated into a single polyprotein.
Source: Kahl, G, The Dictionary of Gene Technology.

Transcriptome By analogy with "genome" , "proteome", and a large number of other "omes" , the set of mRNA transcripts that is present in a cell. Unlike the genome, but like the proteome, an individual organism's transcriptome is not constant but varies according to cell type, developmental stage and conditions (e.g., a disease state or the presence of a drug). However, the correlation between the transcriptome and the proteome is not particularly strong and the proteome is, self-evidently, more indicative of the metabolic processes that are taking place in the cell.

Transcripton *See* Transcription Unit

Transduction The transmission of a signal from the exterior surface of a cell or organelle into the interior of that system, leading to an internal response to the external signal. Signal transduction is initiated by a ligand binding to a surface receptor and carried out by a cascade of enzyme activity.

Transfection The uptake of viral nucleic acid by bacterial cells or speroplasts, resulting in the production of a complete virus. Alternatively, the integration of foreign DNA into the genome of cultured animal or plant cells via direct gene transfer.
Source: Kahl, G, The Dictionary of Gene Technology.

Transgene Any gene that has been transferred from one organism to another organism of a different species. The transformed organism is known as a transgenic organism. Transgenes may not be expressed, or may be expressed at very low levels, in the host organism. Transgenic modification must be strictly controlled by law.

Translation The process of protein synthesis at the ribosome is termed the translation of the RNA sequence into protein. The sequence of the resulting polypeptide is determined from that of the original RNA molecule via the genetic code. Although one code is used almost universally, alternate codes are used in mitochondria and some groups of organisms. The process of protein translation is a complex one in which the ribosome operates as a molecular machine.

Translocation The stepwise, codon-to-codon advance of a ribosome along a messenger RNA sequence with simultaneous transfer of the peptidyl-RNA from the A site to the P site of the ribosome. Each step exposes an mRNA codon for base pairing with its specific tRNA anticodon. Alternatively, any change in the position of a specific chromosome segment either within the chromosome ("shift") or to another nonhomologous chromosome (interchromosomal translocation).
Source: Kahl, G, The Dictionary of Gene Technology.

Transmission-disequilibrium Test A test of the role of genetic factors in disease states in which the genotypes of cases of a disease are compared to those of their parents to discover whether a genetic variant or marker is inherited by cases at frequencies higher than would be expected using classical Mendelian genetics. If the allele or marker is, in fact, transmitted in excess of what would be expected in cases of disease, it indicates that the allele is a risk factor for the disease.

Transposable Element, Mobile Element *See* Transposon

Transposon Generally, any sequence or segment of DNA that can change its location within a genome. However, in the strictest usage the term "transposon" is restricted to use in prokaryotes, with similar sequences in eukaryotes being termed "transposon-like elements". A transposon is flanked by short inverted repeat sequences; it encodes an enzyme that catalyzes its excision from its first site and insertion in a new site. Transposons can be used in the construction of certain types of cloning vectors.

Trans-splicing The ligation of exons from two different mRNA molecules to form one messenger RNA with a different combination of coding sequences that will therefore be translated into a different protein. Much of the complexity of vertebrate proteomes arises from the formation of multiple proteins from a simple gene set using mechanisms such as this one.
Source: Kahl, G, The Dictionary of Gene Technology.

Trinucleotide Repeat Expansion A sequence of three bases that is repeated a large and variable number of times at a specific position of a chromosome (and thus, a special case of microsatellite). The repeated sequence may occur in coding or noncoding DNA; where it occures in coding DNA, it gives rise to an amino acid repeat. Several rare single gene disorders arise from an expansion in a trinucleotide repeat. The best known of these is Huntington's disease, where the expansion is of the trinucleotide CAG in a coding region and therefore of the amino acid glutamine.

Trisomy The presence of three chromosomes of the same type instead of two in a diploid genome. It arises when one chromosome fails to segregate during meiosis. In humans, most trisomies are incompatible with life, but people with trisomy 21 (three copies of chromosome 21) can lead fairly satisfying lives, albeit with the mental and physical disabilities characteristic of Down's syndrome. Babies born with some other trisomies, including trisomy 13, may live a few months.

Tropism Tropism, in general, is the involuntary response of an organism to a stimulus. Viral tropism is the interaction between the virus and its host, and it can hamper gene therapy with viral vectors. Scientists are developing methods of modifying and decreasing tropism in viral vectors.

Tryptic Peptide *See* Proteolytic Peptide

Tumour Suppressor Gene Genes that code for signal transduction proteins that send signals that inhibit cell growth and division are known as tumor suppressor genes; they are, therefore, the opposite of oncogenes. When tumor suppressor genes are mutated they may lose their functionality, leading to a loss of control of cell proliferation and, potentially, the development of cancer.

Twilight Zone The accuracy of a model of the three-dimensional structure of a protein built from the structure of a similar sequence will depend on the percentage identity between the sequences. Between about 10% and 25–30% sequence identity, the degree of homology (evolutionary relationship) between the sequences cannot be inferred from the identity value alone, although a clear evolutionary relationship may be deduced from other means. In this case, the proteins are said to fall within the twilight zone, and successful homology modeling may not be possible.

Two-dimensional Gel Electrophoresis *See* 2D-PAGE

Two Hybrid *See* Yeast Two Hybrid

Underspliced Transcript If a pre-mRNA transcript is processed by fewer splicing events than would be required to produce the correct, mature mRNAs, that transcript is described as underspliced. This frequently occurs in viral processing; for example, the HIV virus originally produces a single transcript that is processed into some 30 mRNAs. If the transcript is underspliced, fewer mature mRNAs will be produced and the daughter virions will not be able to assemble.

Uniparental Disomy A genetic condition in which two copies of one or more chromosomes are inherited from one parent and none from the other parent, with the chromosome number remaining normal. The condition may be termed maternal or paternal uniparental disomy depending on the parent that provided both chromosomes. It may be silent (with the child appearing phenotypically normal); alternatively, it may result in developmental defects due to abnormal imprinting.

Untranslated Region, Untranslated Sequence *See* UTR

Upstream Toward the 5′ end of a DNA sequence. The term is most often used for sequence that is located 5′ of the coding sequence of a gene. The 5′-most region of that sequence that is transcribed into the pre-mRNA (but not translated into protein) is known as the 5′-untranslated region (5′-UTR). Control sequences that are bound by transcription factors and that are located upstream of the 5′-UTR are never transcribed into mRNA.

UTR Portions of sequence that are transcribed into RNA, but not translated into protein. Each transcribed gene includes a sequence upstream of the start codon (leader sequence, 5′ untranslated region or 5′-UTR) and one downstream of the stop codon (trailer sequence, 3′ untranslated region or 3′-UTR). Untranslated regions contain sequences that control expression. The poly-A tail is not part of the trailer sequence as it is not part of the original gene: it is added to the 3′ end of the trailer sequence after transcription.

Vector A plasmid or phage cloning vehicle specially constructed to achieve efficient transcription of a cloned DNA fragment and translation of its mRNA into protein. Cloning vectors often contain an expression cassette including a highly active promoter, to aid efficient gene expression. Genome sequences may be contaminated by vector sequence; this may be tested for by comparing the new genome sequence with a database of known vector sequences.
Source: Kahl, G, The Encyclopedia of Gene Technology.

Viral Capsid *See* Capsid

Viral Tropism *See* Tropism

Virulence Factor A gene or gene cluster in a microbial pathogen which increases the virulence of that pathogen to its human or animal host. Many virulence factors have been transferred between bacterial species via plasmids. Some very pathogenic bacteria, such as Vibrio cholerae (the causative agent of cholera) have been shown to contain “systems” of toxicity comprising 40 or more protein toxins and virulence factors.

Weight Matrix A statistical model used in sequence analysis in which each position in the sequence is modeled independently of the others. Typically, a score is allocated to each amino acid (or base) based on the likelihood of that amino acid (or base) being found at that position in the feature under consideration.

Western Blotting A technique, analogous to Southern blotting, for the detection of specific proteins that have been separated by 2D gel electrophoresis or a similar technique. The proteins are transferred to a membrane and visualized using specific radioactively labeled, fluorescence-conjugated or enzyme-conjugated antibodies.
Source: Kahl, G, The Dictionary of Gene Technology.

Whole Genome Shotgun, WGS *See* Shotgun Sequencing

Window *See* Specificity Window

Workflow In general terms, workflow is simply how a work procedure is organized. It is used in bioinformatics largely in applications that consist of a large number of relatively small or simple calculations, with later analyses chosen as a result of earlier ones. In these cases, workflow software may be used to automate at least some of the tasks and decisions. Examples might include the prediction of protein localization or immunogenicity from a sequence.

Yeast Two Hybrid A relatively new, powerful technique for detecting interactions between proteins. It is based on the dual-module composition of yeast transcriptional activators such as GAL4. The protein under test is linked (hybridized) to the DNA binding domain of GAL4, and a library of proteins to the GAL4 activation domain. DNA transcription only occurs if there is an interaction between the test protein and one of the library proteins.

z score *See* z-score

z-score A statistical parameter defined as the difference between a score achieved for one variable in a set and the mean score for the whole set, divided by the standard deviation in the scores. A high z-score indicates that the score for a particular variable is an outlier that may be of statistical significance (e.g., indicating a match). This concept is often used in protein fold recognition, where it is used to calculate whether there is a statistically significant match between a sequence and one particular fold when it is compared to the whole database of possible folds.
